⑫ The study of SUDs and their treatment is relatively new, and the terminology surrounding SUDs is progressing quickly. Diagnosis is rather straightforward within the context of the *DSM-5* diagnostic criteria. What is not straightforward is some of the terminology and phrasing surrounding SUD. Accurate, patient-focused, and non-judgmental language is a key factor to securing patient engagement and participation. According to data from the NSDUH and MTFS, substance use is still increasing within the US population. The growing financial cost and human suffering caused by this group of disorders will require substantial healthcare resources including research and clinical implementation of therapies as well as even more substantial resources provided by the public health domain to help stem the tide of the mounting problem.

ABBREVIATIONS

ABCD	Adolescent Brain Cognitive Development Study
ASAM	American Society of Addiction Medicine
AUD	alcohol use disorder
AUDIT	Alcohol use disorder identification test
BP	blood pressure
CIWA-Ar	Clinical Institute Withdrawal Assessment – Revised
CIWA-B	Clinical Institute Withdrawal Assessment Scale – Benzodiazepines
COWS	Clinical Opiate Withdrawal Score
CUDIT-R	The Cannabis Use Disorder Identification Test – Revised
DAST	Drug Abuse Screen Test
DAST-A	Drug Abuse Screen Test for Adolescents
DDTAG	Diagnostic Terminology Action Group
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders, 5th Edition*
FTND	Fagerström test for nicotine dependence
HIV	human immunodeficiency virus
HR	heart rate
IMF	illicitly manufactured fentanyl
LSD	lysergic acid diethylamide
MAT	medication-assisted therapy
MTFS	Monitoring the Future Study
NIDA	National Institute on Drug Abuse
NSDUH	National Survey on Drug Use and Health
OOWS	Objective Opiate Withdrawal Scale
OTC	over-the-counter
OUD	opioid use disorder
PDMP	Prescriptions drug monitoring program

QoL	quality of life
RR	respiratory rate
SADQ-C	Severity of Alcohol Dependence Questionnaire
SAMHSA	Substance Abuse and Mental Health Services Administration
SCr	serum creatinine
SOWS	Subjective Opiate Withdrawal Scale
STI	sexually transmitted infection
SUD	substance use disorder
UDS	urine drug screening
WHO	World Health Organization

SELF-ASSESSMENT QUESTIONS

1. The annual cost of prescription drug misuse is estimated to be how much annually?
    - A. $25 billion
    - B. $78 billion
    - C. $250 billion
    - D. $780 billion
2. What is the magnitude of risk for cannabis use disorder in individuals that start using before the age of 18:
    - A. Two times the risk
    - B. Four times the risk
    - C. Seven times the risk
    - D. Ten times the risk
3. According to the NSDUH what is the most commonly encountered substance within the past month for people over the age of 12 years?
    - A. Cannabis
    - B. Nicotine
    - C. Alcohol
    - D. Prescription opioids
4. From 2018 to 2019, what was the percent increase in individuals who used cannabis?

   A. 10%

   B. 29%

   C. 59%

   D. 109%

5. Which of the following is a question from the CAGE questionnaire, used to assess whether a patient may display traits consistent with AUD?

   A. Have you ever felt the need to switch from wine and/or spirits to beer?

   B. Have people annoyed you by criticizing your drinking?

   C. Has your spouse ever felt guilty about your drinking?

   D. Do you need to have a drink each night before bed?

6. What term is defined as decrease in response to a drug dose that occurs with continued use?

   A. Physical dependence

   B. Addiction

   C. Tolerance

   D. Withdrawal

7. What term is defined as a state of neurological adaptation that is manifested by a drug class–specific syndrome produced by abrupt cessation, dose reduction, and/or administration of an antagonist?

   A. Physical dependence

   B. Addiction

   C. Tolerance

   D. Withdrawal

8. Which of the following assessments is a symptom-triggered scale for assessing withdrawal from alcohol?

   A. The SADQ-C

   B. The FTND

   C. The COWS

   D. The CIWA-Ar

9. Which of the following rating scales can be used for the assessment of cannabis use disorder?

   A. The FTND

   B. The COWS

   C. The CUDIT-R

   D. The CAGE

10. Which of the following scales has been developed for use in adolescents?

    A. The CAGE

    B. The CRAFFT

    C. The AUDIT

    D. The OOWS

11. Why is the term medication-assisted therapy or MAT no longer preferred?

    A. NIDA has recommended against its use.

    B. It is not accurate, as pharmacotherapy for SUD does not really assist with treatment, rather it is a treatment.

    C. Patient groups like narcotic anonymous released a statement against its use.

    D. It was not broad enough, as it only applies to pharmacotherapy for AUD.

12. What is driving the change to use new terms when describing a SUD?

    A. The previously used terms were old.

    B. The previously used terms were not accurate.

    C. The previously used terms perpetuated stigma.

    D. The previously used terms were not endorsed by the WHO.

13. Which of the following criteria provided by the *DSM-5* describe impaired control?

    A. Continued use of substance despite persistent recurrent physical harm.

    B. The need for increased amount of the substance to achieve the desired result.

    C. Continued use despite persistent social or interpersonal problems.

    D. Considerable amount of time is spent obtaining substance.

14. Which of the following criteria provided by the *DSM-5* describe risky use?

    A. Substance is taken in larger amounts than intended.

    B. Use is continued despite failure to fulfill major obligations at home.

    C. Recurrent substance use in situations that can result in increased risk of physical harm

    D. Strong desire to use substance

15. Which of the following criteria provided by the *DSM-5* describe Pharmacological Indicators?

    A. Use of a substance or similar substance to relieve or avoid withdrawal symptoms

    B. Continued use despite knowledge of psychological harm worsened by the substance

    C. Considerable amount of time spent recovering from use of the substance

D. Desire to seek out treatment of substance use

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** The annual cost of prescription drug misuse alone is estimated at 78.5 billion dollars, of which over 30% was attributed to an increase in healthcare and substance-related disorder treatment costs. See section "Introduction."

2. **C.** The data suggests that up to 30% of those who use cannabis may develop a use disorder, and that this risk is seven times higher in those who start using before the age of 18 years. See section "Introduction."

3. **C.** According to the NSDUH, alcohol is the most common substance with 50.8% (139.7 million) reporting drinking in the month prior. See section "National Survey on Drug Use and Health."

4. **D.** Use of cannabis is increasing. From 2018 to 2019, the number of people older than 12 who initiated cannabis use in the year prior increased from 2.2 million to 3.5 million, which translates to a 59% increase. See section "National Survey on Drug Use and Health."

5. **B.** Of the four answer given, only B is one of the questions included as part of the CAGE assessment for AUD (see Table e84-1).

6. **C.** The definition of tolerance is a decrease in response to a drug dose that occurs with continued use (see Table e84-3).

7. **D.** With repeated exposure, a hyper-excitable state can result when a substance is withdrawn. The onset, duration, and severity of withdrawal may differ depending on the substance used, chronicity of use, and amount consumed (see Table e84-3).

8. **D.** The CIWA-Ar allows for symptom-triggered treatment of alcohol withdrawal to assess severity and avoid progression to more severe stages of withdrawal (see Table e84-1).

9. **C.** The CUDIT-R is an eight-question scale that includes responses that are answered based on a four-point response (see Table e84-1).

10. **B.** The CRAFFT is a structured interview scale that is also used for children and adolescents to assess for general substance use disorder (see Table e84-1).

11. **B.** The preferred term is medication treatment for SUD instead of medication-assisted treatment because pharmacotherapy for SUD is treatment; it does not assist (see Table e84-3).

12. **C.** These changes are being advocated for individuals suffering from an SUD to reduce stigma and help them maintain dignity as whole human beings (see Table e84-3).

13. **D.** A specific behavior associated with impaired control according to the *DSM-5* definition is when a considerable amount of time is spent obtaining substance, using substance, or recovering from use of substance (see Table e84-2).

14. **C.** A specific behavior associated with risky use according to the *DSM-5* definition is continued use of substance despite knowledge of persistent or recurrent physical or psychological harm that was caused or worsened by the substance (see Table e84-2).

15. **A.** Use of a substance or a similar substance to relieve or avoid withdrawal symptoms is considered a pharmacological indicator according to the *DSM-5* criteria (see Table e84-2).

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter e93: Developmental Disabilities

Steven R. Erickson

KEY CONCEPTS

KEY CONCEPTS

① People with intellectual and developmental disabilities (IDD) have higher incidence of mental illness and challenging behaviors, with dual diagnoses being common.

② Persons diagnosed with Down syndrome (DS) can be at increased risk for medical and psychiatric comorbidities.

③ People with IDD experience high rates of polypharmacy and polypsychotropic medication use. Assessment should include physical disorders, as well as social and environmental factors complicating their care.

④ People with DS have higher rates of Alzheimer-type dementia. A thorough evaluation is needed to differentiate between depression and Alzheimer disease (AD).

⑤ Treatment plans for persons with autism spectrum disorder (ASD) focus on increasing social interactions, improving verbal and nonverbal communication, and minimizing the occurrence or impact of ritualistic, repetitive behaviors and other related mood and behavioral challenges (eg, over activity, irritability, and self-injury).

⑥ Many purported pharmacologic and nonpharmacologic treatments for ASD lack objective evidence-based support.

⑦ A structured teaching approach focusing on increasing social communication and integration with peers is needed when providing services to persons with ASD.

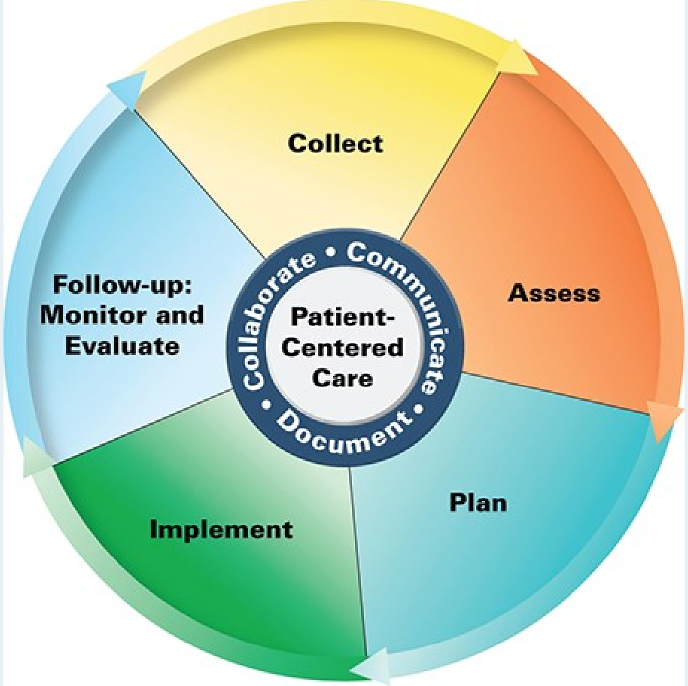
⑧ Nonpharmacologic interventions for sleep disturbances in individuals diagnosed with ASD should be implemented prior to pharmacotherapy considerations.

⑨ Psychopharmacologic treatment planning should include monitoring of objective, measurable medication-responsive target behaviors and assessment of potential adverse effects, which are of critical importance when treating the behavioral challenges of ASD. Furthermore, the response of individuals to pharmacotherapy is highly variable.

⑩ The use of FDA-approved medication for off-label indications is an acceptable clinical practice if founded on evidence-based research and includes informed consent.

PATIENT CARE PROCESS

Patient Care Process for Intellectual and Developmental Disabilities



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Involve the patient and one or more caregivers in this process
- Patient characteristics such as age, sex, pregnancy status
- Past medical and psychological history
- Previous life events (eg, changes in living situation)
- Social history (tobacco/ethanol, substance use or misuse) and dietary habits
- Social and community-based activities
- Current prescription and nonprescription medications and supplements

Assess

- Contraindications to potential medications
- Psychotropic medication already prescribed
- Presence of adverse effects from medications
- Physical causes for challenging behaviors such as constipation, gastroesophageal reflux, seizure, aspiration, pain including dental-related pain, sleeping problems (Table e93-1)
- Risk or evidence of harm to self, others, or property
- Frequency of challenging behavior
- Patient's preference for a type of therapy if appropriate and identify those involved in the patient's medication use process

Plan*

- Choose medication with the strongest evidence and minimal adverse effects (Table e93-2)
- Determine potential medication interactions with other medications
- Use supported decision making, which includes patient preferences, when able
- Education for patient and caregivers
- Develop non-medication intervention based on social and personal factors
- Type of prescription medication insurance and insurance-related regulations in choice of medication

Implement*

- Provide patient education to patient and caregiver(s)
- Work to understand issues related to medication adherence. Choose dosage form that will reduce the likelihood of nonadherence

Follow-up: Monitor and Evaluate*

- Reduction in frequency and severity of challenging behaviors
- Presence of adverse effects (Table e93-2)
- Patient adherence to therapy
- Patient's ability to engage in activities in the community
- Caregiver(s) understanding of therapy
- medication interactions with other medications

**Collaborate with patients, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Compare and contrast the Patient Care Process and the assessment and follow-up tools available on the website for “Healthcare for Adults with Intellectual and Developmental Disabilities. Toolkit for Primary Care Providers.” https://iddtoolkit.vkcsites.org/

Behavioral Problems and Emotional Concerns-Primary Care Provider Checklist

Psychiatric Symptoms and Behavior Checklist

Psychotropic Medication Checklist

Management Plan

Compare and contrast the criteria for each step of the PCP with those of the Toolkit Behavioral and Mental Health Issues “Behavioral Problems and Emotional Concerns-Provider Checklist,” the “Risk Assessment Tools for Adults with IDD in Behavioral Crisis,” and the “Psychotropic Medication Checklist.” This activity will help you envision the important points to assess when consulting on a patient who has an IDD and challenging behavior.

INTRODUCTION

Developmental disabilities (DD) are chronic disabilities that can be cognitive, physical, or both. They appear before the age of 22 and are likely to be lifelong.[1] Some DDs are largely physical challenges, such as cerebral palsy or seizure disorders, and some individuals may have a condition that includes both a physical and an intellectual disability. Intellectual disability (ID) is a disability characterized by significant limitations in both intellectual functioning and adaptive behavior, which covers many everyday social and practical skills.[2] This chapter will use the term "intellectual or developmental disabilities" (IDD) to refer to people who have conditions associated with DD, ID, or both.

EPIDEMIOLOGY

Down syndrome and autism spectrum disorder are several of the more common diagnoses which make up IDD. About 1.5% to 2.5% of the US population is living with some form of IDD.[3] The actual frequency and per cent of the US population characterized as having IDD varies based on the data source and the definition used. According to the 2010 US Census Bureau, 1.2 million adults (0.5%) had an ID and 944,000 (0.4%) had a DD.[4] Globally, the prevalence of ID is about 1% of the population.[5] People with IDD primarily live in the community in living situations that include living with family (71%), group homes, or in supported living arrangements (eg, living by themselves or with one or two roommates with an aid). Only 13% of adults with IDD live in supervised residential settings.[6]

① People with IDD often have some degree of cognitive impairment that may limit their ability to be a collaborative partner in the medication use process, increasing their risk for medication-related problems. Furthermore, those with IDD generally have a high burden of illness which often leads to the person taking multiple medications.[7] Compared to the general population, these complex medication regimens increase the individual's risk for adverse events.[8] Caregivers provide a wide range of support to the person with IDD, depending on the functional ability of the person, including assisting them in navigating the medication use process.[3] In a 2013 population health survey of people who have IDD, 88.3% of people between the ages of 18 and 39 years and 94.7% of those over age 60 years were taking a chronic medication.[9] The prevalence of polypharmacy, with five or more medications, ranged from 30.4% to 45.5% of people who have IDD, with higher rates being seen in older people.

Mental Illness/Dual Diagnosis

Although age-related chronic illness develops in people with IDD similarly to the general population, some conditions may be more prevalent, or occur at an earlier age. The focus of this chapter is on the mental health and behavioral issues that occur in people with IDD. For the purpose of this chapter, the term "dual diagnosis" refers to a person with IDD and who also has a comorbid mental illness. The prevalence of mental disorders in people with IDD is higher than in the general population. Also, challenging behaviors such as aggression or self-injurious behaviors are seen in some people with IDD and are strongly associated with psychotropic medication prescribing, often with multiple psychotropic medications.[10] Psychiatric disorders in persons with an ID, such as depression and anxiety, may result from environmental variables (eg, transitions from family home to group home, change in caregivers), personal variables (eg, age, level of disability, comorbid medical conditions), and the extent to which the individual can cope. The association of life events with depression and anxiety was researched in a community-based population of patients with IDD receiving services from three organizations. Almost all of the subjects (99.1%) had been exposed to at least one life event during the prior 12-month period, with older subjects experiencing more events.[11] In general, more episodes of major depression, generalized anxiety disorder, and panic disorder were associated with a greater number of negative life events. Therefore, clinicians must be aware of the influence of negative life events on a person with IDD when assessing reasons for challenging behaviors.

The prevalence estimates of mental illness or challenging behaviors in people with IDD range from 30% to 70%.[12] The range of findings can be attributed to a variety of factors including differences in population sampling and methodologies used in identifying psychiatric disorders in persons with IDD. Psychiatric disorders may manifest differently among individuals with IDD compared to the general population. Estimates of the prevalence of mental illness for patients with IDD may not be entirely accurate, due to difficulties applying diagnostic criteria, difficulty accessing services, and clinical presentation that may be difficult to interpret.[13] One study of 1,023 people with IDD, which employed a comprehensive individualized clinical assessment, revealed a rate of mental illness of 40.9%.[14] The National Core Indicators project identified a rate for mental illness or psychiatric diagnosis of 66% ($N = 19, 657$) for adults who have IDD.[15] The prevalence of challenging behaviors in people with IDD is also high, with percentage of populations varying from over 5% to 17%.[16]

Challenging/Self-Injurious Behaviors

Challenging behaviors may be seen in patients with IDD and include aggression, self-injury, and property destruction that is often lifelong and can result in negative outcomes such as physical injury and social isolation.[17–19] Importantly, challenging behaviors serve different functions and many factors contribute to their occurrence.[20] Mental health disorders and challenging behavior in people with IDD may be associated with sensory impairments, negative life events, lack of suitable supports (eg, emotional, social, community, work, and recreational), stress, and limited coping capacity.[21–23] Challenging behaviors may also be associated with early victimization, non-enriched and restrictive environments during both childhood and adulthood, traumatic brain injury, skill deficiencies in anger management, poor social skills, communication deficits, and psychopathology. Symptoms related to medical causes or medication-related adverse events may be expressed behaviorally and misinterpreted and reported as challenging behavior.[24]

About 10% to 15% of people with IDD engage in some form of challenging behavior,[25] such as self-injurious behavior (SIB) which is defined as behavior in which a person harms or attempts to harm themself deliberately and physically. Examples include head banging, self-biting, and self-scratching. The prevalence rate of SIB varies from 4% to 23% of people with ID.[26] According to the results of a study using the National Core Indicators database (2015–2016), 23.2% of adults surveyed who have IDD needed some or extensive support for SIB.[27] Individuals who required at least some support for SIB were found to have fewer relationships, less inclusion in their communities, and poorer employment outcomes. Notably, SIB, when present, may occur persistently over time and may be associated with a number of causes such as genetic, biological, psychological, environmental, or a combination.[28] It is also found more commonly in conditions such as Fragile X syndrome, Prader–Willi syndrome, Cri du Chat syndrome, and Lesch Nyhan syndrome.[26] Challenging behavior should not be considered a problem associated with an individual, but should be regarded as the result of an interaction between the individual and their environment. The use of positive behavioral supports is gaining acceptance as an alternative form of treatment for SIB.[29] When working with patients who have IDD and mental illness and/or challenging behaviors, clinicians can screen for sensory impairments, negative social circumstances, stressful life events, and coping capacity. Family and caregivers may be counseled on the value of promoting friendships, social networks, and accommodations for inclusion and participation to decrease isolation and loneliness.[30,31] Antipsychotic medications are often prescribed to control challenging behaviors, often before nonpharmacologic intervention or with no long-term planned tapering.[32] The combination of poor communication skills, co-occurring mental illness, and severity of ID all contribute to the use of psychotropic medication to control challenging behaviors.[24]

Diagnostic overshadowing is a potential cause of mis- or under-diagnosis of mental illness in people with ID.[33,34] This refers to clinicians overlooking or minimizing the signs of psychiatric disturbances in a person with an ID, and attributing signs and symptoms of mental illness to the cause of IDD. Another problem of diagnostic overshadowing is misinterpreting the symptoms of a somatic medical condition to that of challenging behavior or mental illness. According to a multiyear observational registry study comparing psychiatric diagnoses and somatic comorbidities of older adults with IDD compared with the general population, the low occurrence rate of somatic diagnoses may be the result of those conditions being overshadowed by the high degree of psychiatric comorbidities.[35]

DOWN SYNDROME

② Down syndrome (DS) is associated with common dysmorphic features and a wide range of medical and psychiatric concerns, including a number of developmental abnormalities. Congenital heart defects, seizure disorders, orthopedic abnormalities, sensory defects, leukemia, disorders of the eye (eg, cataracts, glaucoma), gastrointestinal (GI) tract, immune system, skin, and thyroid gland are all associated with DS. Persons diagnosed with DS also have a high probability (30%) of early-onset Alzheimer disease (AD) (See later section).[36] DS is one of the most common conditions associated with IDD.[37] The live birth prevalence is approximately 1 in 700 live births.[38]

ETIOLOGY

Chromosomal analysis has identified the etiology of DS as the presence of an extra chromosome 21, which has led to the alternative name of trisomy 21, as this represents one of the most studied abnormal chromosomal conditions. Chromosomes naturally divide and separate in a process known as disjunction during meiotic division. However, in DS, the chromosomes fail to fully separate and both chromosomes remain in the same cell. The end result is an abnormal number of chromosomes on each strand. For many years, advanced maternal age has been recognized to positively correlate with an increased risk for DS, particularly over age 35 years.[39] Consideration has also been given to paternal age as data shows that for couples with younger fathers, the odds of having a child with DS were increased almost twofold.[40] Additionally, it has been theorized that two variables, lack of maternal folic acid supplementation and genetic variability that decrease enzymatic processes in folate pathways, may negatively impact meiotic nondisjunction of chromosome 21. However, the National Down Syndrome Project found no association between folate supplementation use and nondisjunction based on younger maternal age (less than 35 year) or ethnicity, but did report an association between older maternal age and a later stage of oocyte meiosis (meiosis II nondisjunction). While these results may explain previously reported finding differences, additional confirmation, controlling for maternal age, is needed.[41]

CLINICAL PRESENTATION

The consequences of this chromosomal variance include characteristic facial features, some degree of ID, hypotonia, an increased risk for congenital heart disease, and early-onset AD.[42,43] The characteristic facial features make children with DS more readily identifiable at birth with ID ranging from mild to severe.[42] In addition, individuals with DS appear to be at risk to develop depression, anxiety, and obsessive–compulsive disorder.[44] The differential diagnosis for mood disorders in all patients with DS should include an evaluation of thyroid function, as the clinical signs and symptoms of hypothyroidism and dementia can mimic some features of depression. The risk of a thyroid disorder as a comorbidity in people with DS is estimated at 4% to 18%.[42] In a study of older Medicare beneficiaries with DS in California, 40% were identified as having dementia. Comorbid conditions were more numerous among those with dementia compared to those with DS without dementia, especially among those younger than 65 years. These conditions included hypothyroidism, anemia, seizure disorder, and weight loss.[45]

CLINICAL PRESENTATION: Down Syndrome

Diagnostic features

- Facial features can suggest DS, but an additional diagnostic evaluation is necessary.
- Degree of ID ranges from mild to severe.
- Growth delays are common.

Common physical characteristics

- Hypotonia can be evident at birth.
- Facial features include flat nasal bridge and profile, with up-slanted eye folds.
- The palate can be narrow and the neck thick and broad.
- Hands are characteristically short and broad.

Other clinical concerns

- Comorbidity with mental illness, challenging behaviors, and self-injurious behavior.
- An increased risk for congenital heart problems; a cardiac evaluation is generally done shortly after birth with periodic follow-up.
- Congenital cataracts, hearing and sight problems, and hypothyroidism are common.
- Leukemia may occur in early childhood.
- Features of AD can present by the third or fourth decade.

TREATMENT

Desired Outcomes

Treatment goals in DS are to identify medical and psychiatric comorbidities, set realistic goals, and provide effective social, environmental, nonpharmacologic, and pharmacologic interventions to improve the quality and length of life.

General Approach to Treatment

Medical screenings in patients with DS should assess for hypothyroidism, cardiac problems, sensory impairments (including hearing loss secondary to chronic otitis media with effusion or vision defects due to congenital cataracts or glaucoma), and GI problems (including constipation and celiac disease).[42] Guidelines for health supervision and anticipatory guidance in infants, children, and adolescents with DS are available through the American Academy of Pediatrics (AAP).[43] Guidelines for the medical care of adults with DS are also available and routine screenings are also recommended throughout the course of life to address psychosocial changes, potential residential or vocational stressors, and the consequences of aging.[38]

Nonpharmacologic Therapy

The use of social supports for both individuals with DS and their family may help in the development of functional adaptive skills and therefore the fulfillment of the potential for the person with DS. Family education and support network development can assist caregivers by providing tools and resources necessary to more effectively manage persons with DS, allowing these persons to achieve their full potential.

Depressive Symptoms and Challenging Behaviors

All mental health treatment modalities available to the general population also apply to those with DS, with nonpharmacologic options for depression including psychotherapy and electroconvulsive therapy (ECT).[42] Information on the effectiveness of ECT in the DS population is limited to case reports. If communication skills are adequate, psychotherapy may also be an option with treatment strategies including psychodynamic and cognitive behavior therapy (CBT). While the applicability of psychotherapy can vary with the level of ID, for persons with mild intellectual impairment and depression, this treatment modality may be beneficial. These current behavioral therapy models are more effective in addressing specific problematic behaviors rather than the underlying emotional problems of persons with ID. Furthermore, the extent to which these strategies translate to persons with DS and more severe ID is not known.[42,46]

Pharmacologic Therapy

Depressive Symptoms

Pharmacotherapy for the treatment of depression in patients with DS follows guidelines used in the general population. For more information on the treatment of depression, see Chapter 88, “Depressive Disorders.” Features of depression commonly seen in persons with DS, in order of frequency, include apathy, disordered sleep, and changes in weight. Difficulty identifying depression in this population is impacted by the level of cognitive impairment, the ability to express abstract concepts (eg, helplessness or hopelessness), and the level of adaptive functioning.[42] Clinical trials focused specifically on this population are few, and most information has been based on small studies or case reports. Efficacy with SSRIs and amitriptyline is reported in the DS population. If psychotic features (eg, delusions, hallucinations) are present, low-dose antipsychotic augmentation is recommended. In the studies reviewed, treatment duration was 2 to 3 years.[42]

As with the treatment of depression in the general population, the medication trial is of appropriate dose and duration before deeming the patient to be a non-responder. Furthermore, ruling out comorbid medical conditions that could contribute to depression is essential.

Challenging Behaviors

③ People with IDD are prescribed psychotropic medications at a rate higher than the general population,[47] which is not only due to an increase in the diagnosis of psychiatric illness within this population, but also because of challenging behaviors not always associated with psychiatric illness. The most common class of medication dispensed was antipsychotics (21.1% of adults with IDD), according to a study of administrative pharmacy claims data of over 52,000 people with IDD.[48] The use of psychotropic medication in adults living in group homes in the Netherlands was also high with the primary reason for use being behavioral issues. The authors hypothesize that the group home staff found it difficult to deal with people who exhibit socially disruptive behavior.[49] In a cross-sectional study conducted in the Netherlands, out of 2,373 adults with ID, 32.2% received antipsychotic medications. In only 22.5% of cases was the antipsychotic ordered for a psychotic disorder or psychotic symptoms. The remainder of the people received antipsychotic medication for behavioral problems.[50] The presence of adverse events in patients with IDD taking psychotropic medications is a challenge, with adverse events reported in 84% of respondents in a small study in the Netherlands. Not only were symptoms reported, but quality of life was found to be lower in patients with adverse events related to medication.[51] A high incidence of movement-related adverse events is prevalent in adults with IDD taking psychotropic medications.[52,53]

Medication management for challenging behaviors or SIB, using risperidone for example, may be effective in both adults and children, with other second-generation antipsychotics having limited evidence to support their use.[54] In general, antipsychotic medication has been used to treat aggression; however, the rationale for the use of these medications is generally lacking. Aggression is a component of a challenging behavior, and ranges in prevalence from 11% to 27% of people with IDD. Similar to SIB, risperidone is the only medication with some evidence to support its use for aggressive behaviors.[54] There are no reliable data to support antidepressants, other antipsychotic or antiseizure medications for the treatment of aggression.[55,56] Before prescribing medication, clinicians should complete an in-depth assessment of the behaviors and consider nonmedication-based management options as part of the plan.

Sleep Disorders

Obstructive sleep apnea rates are estimated at 50% to 75% in the DS population.[42] Daytime drowsiness and problematic behaviors may be indicative of both an affective disorder, such as depression, and a medical condition secondary to DS. A comprehensive evaluation, including the impact of obesity on sleep, is needed prior to the addition of pharmacotherapy. However, before adding new medication, the medication list for each patient should be carefully reviewed for potential medication interactions and medication–disease contraindications. Parasomnias have been reported with some agents (eg, zolpidem),[57] and the use of medication with this potential effect may require additional monitoring by caregivers, although the frequency of this effect has not been well documented.[58] More information regarding sleep disorders, in general, can be found in Chapter 92, "Sleep Disorders."

ALZHEIMER DISEASE IN DOWN SYNDROME

④ Persons with DS are at greater risk for AD with increased age, with the proportion of the population affected doubling every 5-year period through 60 years old. Approximately half of people with DS at age 60 have Alzheimer associated dementia, and by age 72 years, the prevalence is 6.

ETIOLOGY

Neuritic plaques and neurofibrillary tangles are the hallmarks of AD. In addition, a gene for amyloid-β precursor protein is located on chromosome 21, which may potentially explain the close relationship between DS and AD regardless of age, gender, and level of ID.[60] While the severity of ID has been theorized to significantly impact the incidence of AD, study results are inconclusive, and the level of ID may limit evaluation. A more extensive discussion of the pathophysiology of AD is beyond the scope of this chapter; more information can be found in Chapter 73.

CLINICAL PRESENTATION

In adults with DS, challenging behaviors, such as aggression, loss of previous skills, and disinhibition, may mark a prodromal presentation of AD. Changes in mood and emotional stability may also present.[61] Assessing changes in functionality and cognition is problematic in this population, particularly in those with greater intellectual impairments. Early studies in this population did not specify the diagnostic criteria used for identification of probable or possible AD. Baseline neurocognitive and behavioral status must be assessed and documented beginning at the age of 40 years, and annually thereafter.[61] To meet the diagnostic criteria, the following are needed: baseline functioning data to assess change, functionality changes not explained by general aging, and progressive decline.[62] Accurate diagnosis requires use of an appropriate assessment scale for those with DS, such as the Dementia Scale for Down Syndrome and the Cambridge Examination for Mental Disorders of Older People with Down Syndrome and Others with Intellectual Disabilities.[62] In persons older than 40 with DS, behavior changes are the primary features of the early stages of dementia. Changes may be seen prior to onset with higher frequencies of fear, sadness, and overall behavioral regression. Diagnostic criteria for AD include changes in memory, language skills, and activities of daily living). In addition, major functional declines may include behavioral disinhibition, stereotypic or ritualistic behavior, and/or apathy.[62] Risk factors for AD in those with DS include age, genetics, gender, estrogen, multimorbidity, and metabolic syndrome, although information has been limited in some areas. Information on the natural progression of cognitive changes in those with DS and AD continues to emerge. It is important to rule out other causes for changes, such as hypothyroidism, found more commonly in persons with DS compared to the general population. Screening for hypothyroidism should be done every 1 to 2 years, with treatment guided by standard thyroid function studies.[61]

TREATMENT

Desired Outcomes

The therapeutic goal of treatment is to maintain functioning and quality of life close to baseline for as long as possible. Approaches to therapy for persons with DS combined with AD include nonpharmacologic and pharmacologic interventions. As with the general population with AD, treatment of AD for those with DS is multimodal and includes the available treatments and supports in order to maintain functionality for as long as possible. Chapter 73 outlines the treatment of AD in the general population, and this chapter specifically discusses AD in a patient with DS.

Nonpharmacologic Treatments

Traditionally, this population receives some level of residential living supports in either the family home, supported living environment, or a residential facility. Including the caregiver along with the patient with DS in assessment and treatment decisions is important to obtain a complete clinical and home-life assessment.

Pharmacologic Treatments

Pharmacologic treatments neither cure nor stop the pathologic changes associated with AD. The goals of pharmacotherapy in persons with DS and AD, as in the general population of AD patients, are to slow the decline in cognitive function and help preserve activities of daily living to the greatest extent possible. The use of cholinesterase inhibitors and an *N*-methyl-D-aspartate receptor antagonist memantine in the DS population has been studied. Although limited trial data exist related to the use of memantine in the DS population over age 40 years, results from a smaller prospective randomized double-blind trial did not find treatment or control group improvements for cognition and functional abilities. In fact, both groups declined.[63]

The use of rivastigmine transdermal patches for Alzheimer dementia in adults with DS has also been evaluated in a pilot study that included 10 patients; however, significant differences between treatment and historial controls were found. Patch-related adverse effects included erythema, rash, tinnitus, and diarrhea. Problems specific to this population included one participant repeatedly removing the rivastigmine patch which was then followed by marked progression of the disease rendering pharmacotherapy unnecessary.[64] Furthermore, small studies using donepezil piracetam, folinic acid, and memantine, all of which target different pathways and receptors, have also failed to show improved cognition in this population.[65]

While additional information regarding the pharmacotherapy of AD can be found in Chapter 73, preexisting medical comorbidities, such as congenital heart defects, or concomitant pharmacotherapy may limit the use of cholinesterase inhibitors in persons with DS. Clinicians are encouraged to monitor patients receiving cholinesterase inhibitors for commonly reported adverse medication effects and the potential for medication interactions.

A potential neurologic comorbidity of concern in the DS population with AD is seizures. Although seizure activity may increase with age, the distribution of seizure onset is trimodal, with the first peak incidence appearing before 1 year of age (40%) and predominantly consisting of infantile spasms. The second peak occurs between the ages of 20 and 30 years old (40%) and the final peak corresponds to the onset of Alzheimer-related dementia (20%).[61] Advancing age and a diagnosis of DS are independent risk factors for seizures.[66] Therefore, monitoring for new-onset seizure activity and medicating with antiseizure medications, as appropriate, are essential. Seizures can impair cognitive functioning, particularly if not well controlled.[66] More information about seizure disorders, in general, can be found in Chapter 75 “Epilepsy.”

EVALUATION OF THERAPEUTIC OUTCOMES

Baseline functioning must be established early in adult life prior to the onset of AD, which generally begins to occur during the fourth decade of life. This can be particularly crucial in individuals without expressive language skills. Follow-up evaluations should be performed before age 40 years (at least once) then annually.[67] If cholinesterase inhibitors are used, evaluations every 2 to 4 months (after achieving a maintenance dose) are recommended to monitor for effectiveness if the anticipated gains have not been observed. Monitoring for potential medication-related adverse effects, including diarrhea, nausea, vomiting, insomnia, and headache, is also essential.

Assessment of therapeutic outcomes for those with DS starts with a thorough multidisciplinary evaluation to establish a baseline problem list, identification of clear therapeutic goals, and valid pharmacotherapeutic rationale to guide medication dosing and adverse medication effect monitoring. An in-depth list of treatment targets, both subjective and objective, is important in persons with DS to assist in evaluation of medication response. Careful monitoring for emergence of potential adverse medication reactions should be regularly conducted and documented as part of ongoing assessment of medication effectiveness and to ensure that adverse medication reactions are not a contributing factor to behavioral changes.

AUTISM SPECTRUM DISORDER

Autism spectrum disorder (ASD) is a behaviorally defined pervasive developmental disorder (PDD), which includes autistic disorder, Asperger’s disorder, or PDD not otherwise specified.[62] These disorders are grouped together and referred to as autism, or ASD by the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5). This section focuses specifically on ASD, which is generally characterized by persistent deficits in social communication and social interaction across multiple contexts as well as restricted, repetitive patterns of behavior, interests, or activities. Symptoms must be present in the early developmental period and cause clinically significant impairment in social, occupational, or other important areas of functioning. The disturbances are not explained by intellectual disability or global developmental delay. The severity of ASD is based on the level of support required for social communication impairments and the degree to which restricted, repetitive patterns of behavior impairs functioning.[62,68] Autism is not a disease but a neurodevelopmental disorder with multiple possible etiologies.[69] The onset is typically younger than 3 years of age and is usually, but not always, associated with some degree of ID.[62]

EPIDEMIOLOGY

There has been a recent increase in the reported prevalence of ASD, with the most recent national estimate being 1:68 children identified with ASD.[69] The reported increased prevalence is primarily related to changing and broadening diagnostic criteria, along with an increased index of suspicion, rather than by an actual increased incidence, as ASD is behaviorally identified, and the diagnostic boundaries are not always clear.[70,71] In addition, inclusion of individuals diagnosed with Asperger’s disorder and PDD-NOS in newer studies may also be contributing to the increase.[70] Some behaviors (eg, stereotypies) seen in persons with ASD can also be seen in individuals without ASD. There is a significant impact of intellectual ability on the expression of ASD symptoms, which results in a lack of homogeneity in clinical expression of the condition.[72] A recent meta-analysis describes the male:female ratio to be closer to 3:1.[73] When present, ID ranges from mild to severe.

ETIOLOGY

The etiology of ASD is attributed to multiple causal factors, including gene mutations, abnormalities in brain development, and genetic–environment interactions.[72] Autism may occur concomitantly with other developmental disorders that have a known genetic basis such as fragile X syndrome, Rett syndrome, and tuberous sclerosis.[71] Current research primarily focuses on genetics and neuropathology. Although a single genetic mutation or variant leading to ASD is yet to be identified, research findings indicate that structural alterations in the genome DNA, may be involved.[74] Autism may occur concomitantly with a seizure disorder[74] and may be associated with gene defects that are also risk factors for schizophrenia and attention-deficit/hyperactivity disorder (ADHD).

Siblings of affected children have a significantly greater risk of having ASD (3%-18.7%) than those in the general population.[75] According to the results from a national volunteer registry (2,920 children, 1,235 families, a minimum of 1 child meeting ASD diagnostic criteria, and a minimum of 1 full sibling), the sibling concordance rate was 10.9%, with an additional 8.9% of the siblings demonstrating language delay with autistic-like speech quality.[75]

An additional research further supported the high heritability of ASD outlining that sibling risk varies based on the sex of the index child: 4% versus 7% for female compared with male. If a second child is diagnosed, the risk for concordance in subsequent siblings increases to between 25% and 30%.[76] Lastly, a recent study examined family and twin population-based data across five countries. A high median heritability of 80.8% for autism was found.[77] Heritability refers to how well differences in people's genes account for differences in their traits, with a value of zero indicating almost all variability in a trait is due to environmental factors with little influence from genetic differences. Additionally, children born to older parents appear to be at higher risk for ASD.[71]

While genetics plays a role in the development of ASD, environmental exposures including toxic chemical exposure, teratogens, perinatal insults, prenatal infections, and copper and zinc levels are all under investigation.[71,78] Immunization with measles/mumps/rubella vaccine has been investigated, and no causal association has been identified.[79] Well-conducted case-control cross-sectional ecological and cohort studies investigating the use of thimerosal, an organomercury compound previously used as a vaccine preservative, found no causal association between thimerosal-containing vaccines and the development of ASD or deficits in neuropsychological function.[79] Receiving the MMR vaccine (measles-mumps-rubella) has not been associated with an increased risk of ASD.[80] The neurotoxic effect of mercury exposure continues to be a hotly debated issue among many advocates for persons with ASD, although there is no support for its use. Clinicians must be well informed on this issue to educate parents and caregivers.

PATHOPHYSIOLOGY

ASD may be considered a condition that results from overall brain reorganization beginning early in development.[72,81] There may be alterations in cerebellar structure and connectivity, limbic system abnormalities, and frontal and temporal lobe cortical alterations.[71] ASD may also be conceptualized as a disordering of long-distance cortical and subcortical under-connectivity with compensatory poorly formed shorter circuit over-connectivity. This may lead to enhanced attention on simple stimuli.[78]

Furthermore, dysfunction of virtually all neural systems in the brain has been proposed at some point as a potential basis of ASD.[82] These changes suggest that ASD affects a functionally diverse and widely distributed set of neural systems, making the disorder far broader in scope than a simple social interaction disorder.[82]

There is also research to support the hypothesis that abnormalities in cholinergic receptors and decreases in the nicotinic receptor binding in the cholinergic system, as well as dysfunction in the GABAergic system, may exist in persons with ASD.[83] Other hypotheses of ASD include functional deficits or changes in serotonergic, glutamateric, GABAergic, dopaminergic, cholinergic, and opiate brain systems.[83,84]

Taken all together these studies outline the many differing and often contradictory hypothesis regarding the pathogenesis of ASD.

CLINICAL PRESENTATION

A multiple-step process has been suggested as a structured approach to differential diagnosis of suspected ASD. As a spectrum disorder, the severity or level of impairment within each of these features may be highly variable. Therefore this structured approach includes a determination of intellectual function and level of language development, followed by assessment of the child's behavior as it relates to chronologic age, mental age, and language age. It is important to identify relevant comorbid medical conditions and the presence of any related contributing psychosocial factors.[71,78,81]

CLINICAL PRESENTATION: Autism Spectrum Disorder

General

- Individuals typically present with delays or abnormalities in social communication/interaction as well as restricted, repetitive patterns of behavior, interests, or activities.

Diagnostic features

- Significant impairment in nonverbal communications.
- Unable to develop peer relationships.
- Lack of spontaneous interactions with people or the environment.
- Developmental delays in communication.
- Inability to use expressive language appropriate to developmental level.
- Lack of developmentally appropriate play.
- Stereotypical or nonfunctional ritualistic behavior.
- Inability to tolerate change.
- Stereotypic or repetitive, nonfunctional motor movements.
- Limited scope of play or interest.

Data from References 61, 85, 86.

Between 2% and 21% of those with ASD also have comorbid seizures, which may increase the risk for greater intellectual impairments.[62,85] Other medical comorbidities commonly reported in this population include sleep disturbances, food intolerances, and GI dysfunction.[87] Persons with Down syndrome, Williams syndrome, and fragile X syndrome may have a greater likelihood of having ASD.[88]

The cardinal features of ASD include sustained impairment of reciprocal social interaction, sustained abnormalities in verbal and nonverbal communication skills, and restricted, repetitive, and stereotypical patterns of behavior, interests, and activities.[62,72] These are primarily manifested as gaze aversion, little/no interest in making friends, preference for solitary activities, repetition of words/phrases, monotone voice, insistence on sameness, and a lack of awareness of other’s feelings.[62,72] In most cases (~75%), there is an associated diagnosis of ID, ranging from mild to profound: approximately 30% function in the mild-to-moderate range of ID, whereas 45% to 50% have severe to profound impairment.[89] The risk for development of ASD increases as the IQ decreases.[89] A few individuals with ASD have unusual abilities called splinter functions or islets of precocity. The most significant of these are evidenced in the autistic savant, in which the individuals can have precocity in mathematic calculations, art, music, or rote memory.[62,89]

In many instances, parents note that they were concerned about the child’s lack of interest in social interactions since birth, but were sure at least by 3 years of age.[62] In a controlled setting, use of an integrated model for screening was effective in diagnosing children before 36 months of age.[90] Original findings of behaviors suggesting the need for an intellectual evaluation included lack of babbling, pointing, or other gestures by 12 months, no single-word language development by 16 months, no two-word language development by 24 months of age, and loss of previously held language or social skills at any age.[72] Earlier intervention is recommended when the early signs and symptoms of ASD are recognized.

It is difficult to determine if ASD is present in persons with severe to profound ID; therefore, a diagnosis is made in such cases when there are qualitative deficits in social and communicative skills and the specific behaviors characteristic of ASD are present.[62] A key central difference between ID and ASD is that persons with ID alone typically relate to adults in a manner consistent with their mental age, use their language to communicate with others, and present with a relatively even profile of impairments without splinter functions.[89]

Although there are no definitive biologic markers for identifying individuals with ASD, a number of medical evaluations should occur at baseline, to assist in distinguishing the diagnosis as ASD and to rule out other disorders. Table e93-1 delineates the parameters to be considered in a medical evaluation for persons suspected of having ASD and the rationale for the assessment.

TABLE e93-1

Medical Screening for Individuals with Autism Spectrum Disorder

Parameter>	Rationale
Health, medical, behavioral, and developmental history	Perform initial screening or confirm diagnosis; identify underlying cause; assess strengths and weaknesses; identify comorbidities; measure head circumference; identify resources needed
Wood's light exam	Identify depigmented macules associated with tuberous sclerosis
Hearing and vision testing	Profound hearing loss can illicit symptoms mimicking ASD (receptive language deficits); most are normal
Heavy metal testing	Perform if there is a history of malnutrition, recurrent vomiting, early onset seizures, dysmorphic features, presence of ID or developmental delays
Genetic testing for karyotype, fragile X, Rett syndrome	Benefits family for genetic counseling purposes; evaluation of siblings, if applicable; review family history for three generations
Test for inborn errors of metabolism/metabolic testing	Indicated in those with a history of lethargy, recurrent vomiting, early seizures, dysmorphic or coarse facial features, ID
CBC, thyroid function testing	CBC if anemia suspected; thyroid function tests to rule out baseline thyroid abnormality that can affect mood/activity level
EEG	Evaluate neurologic findings that cannot be explained by the diagnosis of ASD alone or in the presence of developmental regression, particularly language
Neuroimaging	Evaluate neurologic findings that cannot be explained by the diagnosis of ASD alone; identify specific neuropathological changes associated with ASD, including brain volume

CBC, complete blood count; EEG, electroencephalograph.

Data from References 79,91,135.

Those individuals with ASD and intelligence quotients (IQs) above 70 who use communicative language by ages 5 to 7 have the best prognoses.[89] Conversely, low IQ scores and failure to develop communicative language by age 5 years correlate with a poorer long-term prognosis.[89] Outcome studies in persons with ASD correlate IQ, particularly verbal IQ, with the ability to be employed and live independently.[91] Studies indicate that high-IQ children with ASD can make positive changes in communication and social domains more effectively over time. The areas less likely to improve are those related to ritualistic and repetitive behaviors.[92] Up to 80% of children diagnosed with ASD continued to experience marked impairment in social interactions as adults and mild-to-moderate ID was reported for approximately 30%.[93]

In addition to the core symptoms of ASD, many persons with this disorder exhibit other significant maladaptive behaviors, such as aggression toward self and others. These behavioral issues can interfere with day-to-day activities and are challenging for the individual, families, and caregivers.[94]

TREATMENT

Desired Outcomes

5 Treatment goals in persons with a diagnosis of ASD are to maximize their ability to lead a full self-directed life through person-centered approaches to care and support. This includes addressing deficits in communication and social interaction using a structured approach and minimizing the impact of restricted behaviors (eg, stereotypies or repetition) appropriate to the level of intellectual ability, language development, and chronologic age. The multimodal treatment plan should address: (a) establishing realistic goals for educational efforts, (b) identifying the presence of behavioral target symptoms for intervention, (c) prioritizing target symptoms and comorbid conditions for intervention, (d) using specific methods of outcome monitoring of functional domains (eg, behavioral skills, adaptive skills, academic skills, social interaction skills, communication skills), and (e) monitoring for efficacy and potential adverse effects of medication (if used). The National Institutes of Health (NIH) suggests that evidence-based treatment strategies include the use of both psychoeducational therapies and medications.[95] An effective, well-designed, multimodal treatment plan that is consistently executed has the most potential to positively shape how an individual with ASD interacts with the environment and improve their quality of life and that of their families and caregivers.

6 After a thorough diagnostic evaluation, treatment planning for the individual with ASD is critical to assure consistency and efficacy of interventions. With the often-severe nature of the behavioral and adaptive problems, many potential treatment modalities lacking results have been proposed for persons with ASD. The two treatment approaches for ASD with evidence-based support and clinical consensus are behavioral/psychoeducational therapies and psychoactive medication intervention[72] as appropriate. All stakeholders (family, educators, caregivers, clinical professionals, and the patient) should be involved in the treatment planning process, and decisions should be evidence-based and individualized to the specific identified needs of the individual. The potential for communication deficits often limits self-reporting of psychopathology. A multifaceted approach to information gathering should include direct observation; interviews with patient, parents, family, caregivers, and teachers; and review of the medical record, including any behavioral rating scale information.

Nonpharmacologic Therapy

7 Appropriately designed, consistently implemented educational services positively impact the acquisition of social, communicative, self-care, and cognitive skills, each of which facilitates the person’s long-term success. Services, such as occupational therapy, physical therapy, and speech pathology, are often integral aspects of an overall educational plan. Because of the pervasive need for sameness in routine, ongoing and consistent year-round educational programming is more effective than intermittent, episodic interventions. Effective language and communication training can lead to generalized improvements in social skills and repetitive behaviors, and thus positively impact other nonspecific maladaptive behavioral problems such as noncompliance, self-injury, and aggression.[72]

Intervention strategies, such as discrete trial training, improve challenging behaviors. Educational techniques include structuring the environment, family training, peer role modeling, and sensory integration to optimize environmental interactions.[72] Applied behavior analytic interventions have funding to support utilization by people with ASD.[94,96]

Pharmacologic Therapy

6 Evidence-based therapy for ASD is limited to the treatment of co-occurring behaviors or diagnosis, and not ASD itself.[72] Many of the studies of psychopharmacologic interventions in persons with ASD have methodologic shortcomings including problems in experimental design and sample size, poorly defined diagnostic criteria, and many clinical outcomes that were limited in duration or of dubious clinical significance. Among a number of scientifically unsupported treatments for ASD is the use of complementary and alternative medicine. According to a study of 540 families of children with ASD, the child/family had tried an average of seven complementary and alternative medicine therapies.[97] Elimination diets in which casein (from dairy products) and/or gluten (from wheat products) are excluded from the diet have no benefit. Other such purported therapies include omega-3 fatty acids and selected herbal remedies, specifically ginkgo biloba. However, controlled trials have no significant differences between omega-3 and ginkgo biloba supplementation compared to placebo.[98]

8 Current research on the neurobiologic basis of ASD is centered on the serotonergic, peptidergic, dopaminergic, and noradrenergic systems. This research has particular applications for insomnia in ASD, as the prevalence of sleep disorders has been reported to range from 44% to 83%.[99] Parents commonly rate sleep disturbance as a significant clinical issue. As with patients without ASD, it is important to determine the underlying etiology of the sleep problem. Behavioral interventions (eg, improved sleep hygiene, eliminating maladaptive sleep habits, and parental education) should be undertaken prior to implementing pharmacotherapy. No medication is approved by the FDA for pediatric insomnia. While controlled trial data are limited, there is support for the use, of melatonin as it has been reported to improve sleep, and specifically, result in shorter sleep onset latencies. When used in ASD, doses range from 0.75 to 6 mg and adverse effects are mild (eg, headaches, GI upset, dizziness).[100] Chapter 92, “Sleep Disorders” outlines the treatment of sleep disorders in greater detail.

9 Aggression to self and others and severe tantrums are a concern, particularly with adults with ASD. In addition to inclusion of nonpharmacologic interventions, pharmacotherapy is frequently utilized. Despite limited evidence-based support, psychoactive medications have been widely used to minimize the frequency and intensity of these behaviors. Clinicians must identify and carefully monitor specific behavioral target symptom response to avoid the practice of overprescribing psychoactive medications.

Antipsychotics

An association between dopamine dysregulation and increased aggression, including self-injury, consistent with animal models, has been proposed.[94] Such findings have led to the use of antipsychotic agents, that act as dopaminergic antagonists, to address aggression and SIB. The first-generation antipsychotic agent with highest short- and long-term safety and efficacy is haloperidol. Target behaviors included impaired learning, anger, mood lability, hyperactivity, and social withdrawal. Although antipsychotic treatment resulted greater improvement in the target behaviors compared with the placebo group, the risk for the development of dyskinesias is high, therefore the newer second-generation antipsychotics are preferred over first-generation agents.[101]

10 As few psychopharmacologic agents have been well studied in this population, and even fewer have received FDA approval, current research has focused on the second-generation antipsychotics. Off-label use of FDA-approved medications (ie, use of an approved medication for an unapproved use) is an acceptable clinical practice when there is evidence-based support for the use of the medication and informed consent is obtained; however, there is a relative lack of robust research in this area at the present time.

Aripiprazole and risperidone are FDA approved to treat the behavioral (eg, irritability) symptoms associated with ASD.[101,102] Both short- and long-term use of orally administered aripiprazole, dosage rang of 2 to 15 mg per day, was effective for irritability in pediatric patients with ASD. Aripiprazole related adverse medication reactions resolved with continued use.[103-106] Weight gain was reported during the first 3 to 6 months, plateauing thereafter.[103] Risperidone has the most evidence-based support for treating behavioral problems associated with ASD and is FDA-approved for treatment of SIB, aggression, temper tantrums, and irritability in children and adolescents with ASD.[72] The efficacy of risperidone in the treatment of irritability associated with ASD was established in several short-term (6-8 weeks), placebo-controlled trials in children and adolescents (aged 5-17 years) who met the DSM-IV criteria for ASD. Significant improvements in outcomes measures such as the Aberrant Behavior Checklist (ABC) and the Clinical Global Impression - Change (CGI-C) scale were seen.[107,108] Short-term studies also have some success in reducing repetitive behavior, aggression, irritability, and overall behavioral symptoms in adults with ASD.[109] The use of olanzapine is supported by limited trial data in children and adolescents with ASD. Trial durations were generally short (6-8 weeks) with small numbers of participants. Positive results are generally reported in CGI; however, the significant weight gain and sedation noted these trials are important considerations in weighing risk versus potential benefit.[72] A post-hoc analysis of the health-related quality of life of pediatric patients receiving aripiprazole improved the scores compared to placebo in three of five subscales, including emotional, social, and cognitive functioning.[110] Aripiprazole reduces irritability, but its behavioral effects have not been examined adequately.[111]

The second-generation antipsychotic agents are less likely to elicit extrapyramidal adverse medication reactions than first-generation agents due to more potency at serotonin 2A (5-HT2A) receptors versus dopamine receptors. However, the second-generation agents have been implicated in weight gain in some persons with ASD.[72] The potential serum prolactin elevation related to risperidone use is of concern as this may lead to amenorrhea, galactorrhea, and osteoporosis in females and gynecomastia and sexual dysfunction in males. The minimum degree of prolactin elevation that is clinically relevant is uncertain, as are the implications for long-term use in a pediatric population. If detected, strategies include evaluating the risk–benefit with continued use, reducing doses, or changing to another agent with less impact on prolactin. Clinicians must monitor for the evidence of potential risperidone-mediated prolactin elevations regardless of whether a prolactin level is obtained.[112] Additional monitoring recommendations for antipsychotic use and the monitoring of adverse effects can be found in Chapter 87 "Schizophrenia."

Selective Serotonin Reuptake Inhibitors

Serotonin synthesis differs between children diagnosed with ASD and children without this diagnosis as 5-hydroxytryptamine (5-HT) synthesis may peak at twice the adult level in developmentally normal children by age 5 years, whereas children with ASD have a more gradual developmental arc with a lower peak.[113] The use of selective serotonin reuptake inhibitors is often associated with a decrease in some of the core behavioral symptoms such as stereotypies, social withdrawal, and rigid adherence to routine. Citalopram, escitalopram, fluoxetine, and fluvoxamine have limited support for use of SSRIs to address behaviors of ASD.[113,114] There is no FDA-approved medication for the core symptoms of ASD. Prior to the inclusion of pharmacotherapy for behavior as a component of the plan, utilization of a multifaceted approach is recommended.[72]

Psychostimulants

ADHD is the most common comorbidity in people with ASD (28.2%).[72] Psychostimulants have been studied in persons with ASD to address hyperactivity, impulsivity, inattention, and ADHD. Pharmacologically these agents block the reuptake of dopamine and norepinephrine, which may support their use in ADHD as their use may correct dysfunction in the regulation of these catecholamines.[112] The largest and most rigorously controlled trial of methylphenidate involved 72 participants, with 74% having a primary diagnosis of ASD. In this placebo-controlled trial, methylphenidate was given in divided doses of 0.125, 0.25, and 0.5 mg/kg (morning and noon doses) with 16 participants not being able to tolerate the 0.5 mg/kg dose phase. All three doses performed better than placebo on improving the core symptoms of ADHD, with the medium dose performing better than the low dose according to the parent and teacher ratings.[115] The doses used in this trial were generally lower since the patients with ASD were unable to tolerate the higher doses commonly used in ADHD patients. In terms of adverse medication reactions, irritability and stereotypic behaviors, GI complains, and sleep disturbances are seen with the higher doses.[116] Another agent, atomoxetine, has been reported to significantly reduce hyperactivity in small trials with a moderate level of adverse effects similar to methylphenidate.[117] The treatment response to psychostimulants varies.[118] The α2-agonists, clonidine and guanfacine, have also been used to treat hyperactivity and agitation in persons with ASD because of their pharmacologic effects on noradrenergic release and transmission. Both agents have FDA approval for treating symptoms associated with ADHD; however, as with many psychoactive medications used in the ASD population, there is a lack of methodologically sound studies supporting use of these agents. Two trials reported positive outcomes with guanfacine when used for the targeted symptoms of inattentiveness and hyperactivity, with global improvements being noted in one.[118] Therefore, aggressive behavior, sleep disturbances, and anxiety may respond to α2 adrenergic receptor agonists with common adverse effects including drowsiness, fatigue, and decreased appetite (Table e93-2).[119] The response to methylphenidate and atomoxetine is less than what is typically observed in patients without ASD, while the response to guanfacine for hyperactivity was greater. On the other hand, adverse effects are more common for guanfacine, while atomoxetine may be better tolerated.[120]

TABLE e93-2

Common Psychotropic Medications Used in Down Syndrome and Austin Spectrum Disorders

Medication>	Indications	Target Symptoms	Common Adverse Medication Reactions
Second-Generation Antipsychotics			
• Risperidone • Aripiprazole	• Self-injurious behavior, aggression, temper tantrums, irritability • (Risperidone and aripiprazole approved for irritability in ASD)	• Irritability, aggression • Aberrant social behavior	• Sedation, drowsiness, medication-induced extrapyramidal reaction • Insomnia, fatigue, parkinsonian-like syndrome, headache • Anxiety, dizziness, drooling • Hyperprolactinemia, weight gain, Increased appetite • Increased serum total and LDL cholesterol, triglycerides, glucose • Decreased HDL cholesterol • Vomiting, constipation, upper abdominal pain, nausea, urinary incontinence • Tremor, nasopharyngitis, cough, rhinorrhea, fever
Cognitive Enhancers			
• Memantine • Donepezil • Rivastigmine	Memory, cognition	Cognition	• Hypertension, hypotension • Dizziness, insomnia, confusion, headache, anxiety, depression, drowsiness, hallucination, pain, aggressive behavior, fatigue, back pain • Weight gain, weight loss (rivastigmine), diarrhea, constipation, vomiting, abdominal pain, urinary incontinence • Cough, dyspnea
Miscellaneous			
• Oxytocin • Vasopressin	• Aberrant social behavior • Social behavior, communication	• Emotion recognition • Eye gaze	Nasal discomfort (intranasal oxytocin), tiredness, irritability, diarrhea
Melatonin	Sleep disorder		Dizziness, enuresis, excessive daytime somnolence, headache, nausea, insomnia, nightmares, and transient depression
• Methylphenidate • Atomoxetine • Clonidine • Guanfacine	Treatment of attention-deficit/hyperactivity disorder (ADHD)	Hyperactivity, inattention	• Insomnia, headache, irritability • Decreased appetite, xerostomia, nausea, early morning awakening • Drowsiness and fatigue (clonidine, guanfacine)

Miscellaneous Agents

Vasopressin, which is thought to influence social behavior, is a closely related hormone to oxytocin. Physiologically the oxytocin and vasopressin receptors are highly expressed in the amygdala, hippocampus, and nucleus accumbens, and play a role in behaviors, bonding, and parental care.[121,122]

Short-term studies of intravenous and intranasal administration of oxytocin showed decreased repetitive behaviors and enhanced social cognition in patients with ASD[123-126]; however, more recent work on intranasal oxytocin provides inconclusive results.[124] The medication balovaptan is an oral agent that inhibits vasopressin V1a from binding to receptors in the brain. Early studies showed the potential to improve social interaction and communication in patients with ASD.[126] However, a 2-year open-label extension study of balovaptan in adults with ASD was terminated early due to lack of efficacy.[127]

The current dearth of evidence-based psychopharmacologic and behavioral research in persons with ASD is being addressed by a network of NIH-funded research centers, including the research units of Pediatric Psychopharmacology, Centers for Programs of Excellence in Autism, and Studies to Advance Autism Research and Treatment. The mission of these units is to foster well-controlled, multicenter, behavioral, and psychopharmacologic intervention studies targeting behavioral symptoms in persons with ASD.

EVALUATION OF THERAPEUTIC OUTCOMES

⑨ Monitoring the safety, efficacy, and tolerability of psychopharmacologic interventions in persons with ASD is imperative to minimize adverse medication-related sequelae and optimize desired therapeutic outcomes. Clinical investigators have used a variety of psychometric assessment instruments in attempts to measure changes in core symptoms such as communication impairment, restricted interests, repetitive, compulsive, ritualistic, or perseverative behaviors, irritability, hyperactivity, and variants of self-injurious behavior. While a comprehensive review of many of these instruments is beyond the scope of this chapter, the Aberrant Behavior Checklist consists of 54 items divided into five domains: irritability, hyperactivity, stereotypic behavior, lethargy, and inappropriate speech. This checklist was designed for assessment of behavioral changes in institutionalized individuals enrolled in pharmacotherapy trials; however, a community-based version is also available.[128,129] In addition, the Children's Yale-Brown Obsessive Compulsive Scale modified for PDDs is a validated scale sensitive to changes in repetitive behavior severity pretreatment and posttreatment.[130]

Intensive monitoring for medication-related adverse effects is critical for individuals with ASD, as self-reporting can be unreliable. Therefore, a caregiver-rated instrument, such as the Monitoring of Side Effects Scale can be useful for this purpose as it is a multisystem, quantitative, and qualitative caregiver assessment that rates the presence or absence and severity of a variety of potential medication-related adverse effects for clinician review.[131] Signs and symptoms are written in layperson language and are listed by body area or system. As such, it is a broad-based screening tool that can be enhanced by side effect–specific scales such as those for akathisia (eg, Barnes Akathisia Scale), extrapyramidal effects (eg, Simpson-Angus Scale), or tardive dyskinesia (eg, Dyskinesia Identification System: Condensed User Scale [DISCUS]).[132-134]

⑨ Use of second-generation antipsychotics has been associated with increased risk of developing metabolic syndrome. Children, and adults, receiving these agents should be monitored for hyperglycemia, dyslipidemia, and weight gain in a manner consistent with the consensus guidelines suggested by the American Diabetes Association and the American Psychiatric Association. For monitoring guidelines, see Chapter 87, "Schizophrenia."

CONCLUSION

Psychotropic medications can be effective for the treatment of mental health conditions for people with IDD. Medication therapy must be coupled with other psychological therapies when a psychiatric disorder is confirmed by comprehensive assessment. Psychotropic medications should be used carefully for people with IDD, as there is increased risk of adverse medication interactions due to a high prevalence of polypharmacy, the patient having atypical responses to psychotropic therapy, and the inability of a person with IDD to describe the harmful or distressing effects of psychotropic therapy other than through changes in behavior.[129] One must remember that when assessing an individual with IDD who is exhibiting mental illness or challenging behaviors, physical-related problems may be underlying. For example, a person with minimal verbal communication may exhibit challenging behavior when experiencing pain from an underlying undetected tumor or broken bone. A complete examination and history taking, including information from caregivers who work with the person, is necessary in order to make an accurate diagnosis and recommendation for treatment.

ABBREVIATIONS

AAP	American Academy of Pediatrics
ABC	Aberrant Behavior Checklist

SELF-ASSESSMENT QUESTIONS

1. Which of the following deficits associated with intellectual disabilities may mask signs of psychiatric disorders?

A. Inattentiveness

B. Functional adaptations related to stress management

C. Syndrome-specific features such as hand-flapping or self-hugging

D. Receptive language skills

2. Advanced age of which direct ancestor(s) is most frequently identified as a risk factor for Down syndrome?

A. Maternal grandmother

B. Paternal

C. Maternal

D. Combined maternal and paternal

3. MJ, a 39-year-old woman diagnosed with Down syndrome and mild-to-moderate intellectual impairment, presents to psychiatric clinic accompanied by her family. Her parents report she has become increasingly irritable over the past 6 months, more socially withdrawn, and lethargic. The family is interested in further assessment and possibly instituting therapy. Based on this information, which would you recommend at this point?

A. Screen for a seizure disorder

B. Screen for a cardiac event

C. Screen for possible fractures

D. Screen for hypothyroidism and depression/anxiety

4. A 5-year-old child experienced normal development until about 2 years of age when her parents noticed she did not talk as much as her peers and did not make good eye contact with her parents. As a toddler she played with her sister, but now prefers solitary play. Parents, teachers, and clinicians now suspect the child meets the criteria for diagnosis of ASD. Which feature would help confirm this diagnosis?

A. Hand wringing

B. Bruxism

C. Temper tantrums

D. Restricted preferences for only certain toys and/or foods, including marked preference for sameness

5. A colleague requests a consult for a 16-year-old patient with Down syndrome recently diagnosed with bipolar disorder and started on lithium. You state that:

A. The evidence suggests no monitoring is needed.

B. A significant causal link exists between these comorbidities.

C. Closer thyroid monitoring may be needed in this patient.

D. Renal function may be impaired in persons with Down syndrome.

6. A child with a confirmed diagnosis of ASD is in your pediatric clinic. What is the most common neurological problem in children with a diagnosis of ASD?

A. Seizure disorder

B. Tourette disorder

C. Rett syndrome

D. Neurogenic scoliosis

7. The parent of a child with ASD complicated by extremely aggressive behaviors asks about a trial of risperidone for these challenging behaviors. Nonpharmacologic strategies have already been implemented with limited success. You discuss this potential medication therapy with the mother and explain that:

A. First-generation antipsychotic agents are less expensive and equally effective as second-generation agents.

B. Secretin may be a better therapeutic option for this child.

C. The parent should check for complementary and alternative medication options as these have strong support for efficacy.

D. Risperidone has the strongest evidence-based results in treating aggressive behaviors associated with ASD.

8. Early diagnosis and appropriate treatment are important for children with ASD in order to:

A. Promote maximal learning, improve behaviors/communications, and engage in recreation/social/occupational activities.

B. Implement pharmacotherapy and titrate the dose as quickly as possible.

C. Justify institutional placement for vocational training opportunities.

D. Enroll the parents and child in support groups and counseling.

9. Parents bring their 18-month-old child to your pediatric clinic. They mention the child does not enjoy playing with his/her siblings, has no interest in his/her parents, and has not begun to speak single words. What guidance should be given to these parents?

A. Refer the family to a developmental evaluation center for a multidisciplinary workup.

B. Minimize their concerns due to the young age of the child and reevaluate in 6 months.

C. Refer the family to a support group for ASD.

D. Discuss neuroimaging to rule out brain pathology or injury.

10. As part of a medical workup for a child with suspected ASD, which of the following is *not* commonly performed?

A. Detailed medical and developmental history

B. Lead or heavy metals testing, especially if pica is present

C. Genetic testing of parents and child

D. Electrocardiography at baseline and in 6 months

11. What clinical condition associated with personality and behavior changes may present in Down syndrome adults?

A. Hypothyroidism

B. Obsessive–compulsive disorder

C. Alzheimer disease

D. Megakaryoblastic leukemia

12. When conducting a face-to-face medication regimen review of a person who has Down syndrome and mild cognitive impairment, the clinician should:

A. Only review a written medication list and medical record since the caregivers will not be able to provide meaningful information.

B. Include the patient to the best of their ability in all lines of questioning.

C. Focus only on the psychotropic medication.

D. Educate only the caregivers when it appears that there is a deficit in understanding medication regimens.

13. A family physician asks you for a recommendation for a sleep agent for an adolescent patient who has autism spectrum disorder and is experiencing sleep problems. Which of the following is the most appropriate recommendation to make?

A. Start zolpidem, 5 mg every bedtime, increasing to 10 mg every bedtime after 2 weeks.

B. Have the patient exercise just before bedtime to induce fatigue.

C. Assess the patient's routine around bedtime to see if changes in activities can be made in an effort to produce a calming environment.

D. Start melatonin oral therapy immediately, as there is strong evidence that this intervention is the most effective intervention for insomnia for people with ASD.

14. Treatment goals in persons with a diagnosis of ASD are to:

A. Maximize their ability to lead a full self-directed life through person-centered approaches to care and support.

B. Completely eliminate repetitive speech patterns.

C. Increase the IQ of the patient.

D. Ensure the patient is prescribed at least one antipsychotic medication in order to prevent the development of new stereotypic symptoms.

15. Which of the following is *not* true regarding psychotropic medication regimens for people with IDD?

A. Medication regimens tend to be more complex.

B. Patients with IDD often rely on other people to manage their medications for them.

C. Patients with IDD have multiple medical problems which lead to polypharmacy.

D. A person with IDD can usually describe harmful or distressing effects of psychotropic therapy.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** All answers may contribute to the masking of psychiatric disorders in people who have IDD. Diagnostic overshadowing is where the clinician assumes a sign or symptom is related to the IDD condition when instead it may actually be the result of an underlying mental illness. People who have

IDD may not be able to communicate or that the ability to cope with stress-related concerns or anxiety, and instead will “act out” in behaviors that may mimic those of mental illness. (Refer to the “Epidemiology” and “Challenging/Self Injurious Behavior” sections.)

2. **C.** Maternal age is the most consistently identified risk factor for Down syndrome, although some studies also implicate paternal age as well. (Refer to the “Down Syndrome” section.)

3. **D.** Hypothyroidism is a common comorbidity in persons with Down syndrome. Anxiety and depression are also seen. As a work-up for Alzheimer’s dementia, examining other causes for changes in behavior are warranted. (Refer to the “Alzheimer’s Disease in Down Syndrome” section.)

4. **D.** There are a number of social and behavioral observations that parents and teachers may see in a child who is suspected of having ASD. Focusing excessive attention on specific objects or toys at the expense of interacting with other toys in a child’s environment is one example. (Refer to “Clinical Presentation” in the “Autism Spectrum Disorder” section.)

5. **C.** People with Down syndrome have a higher likelihood of experiencing hypothyroidism compared to the general population. (Refer to the “Down Syndrome/Clinical Presentation” section.)

6. **A.** Prevalence of seizure disorders in people with ASD is between 2% and 21% and is higher than the general population. (Refer to the “Clinical Presentation” section.)

7. **D.** Of all the first- and second-generation antipsychotic agents, risperidone has the strongest support for the use for controlling aggressive and challenging behaviors in pediatric and adult patients who have ASD. (Refer to “Antipsychotics” in the “Autism Spectrum Disorder” section.)

8. **A.** Early diagnosis of ASD is essential to be able to engage the patient in the evidence-based behavioral programs. Patients who initiated behavioral programs early, as well as connecting families to support services, can lead to improved outcomes. (Refer to “Nonpharmacological Therapy” in the “Autism Spectrum Disorder” section.)

9. **A.** Multidisciplinary practices that include pediatricians, social workers, psychologists, and behavioral specialists can identify treatment options for the patient and their family. (Refer to the “Clinical Presentation” section.)

10. **D.** Causes of ASD are still relatively unknown but many are hypothesized. As well, other childhood medical conditions may have similar symptoms as seen with ASD. Ruling out other causes for symptoms is important to differentiate various diagnoses and to treat the causes once identified. (Refer to the “Autism Spectrum Disorder,” Table e93-1.)

11. **C.** Adults with Down syndrome have a higher likelihood of developing Alzheimer disease compared to the general population. Changes in behavior, decreased participation in normal activities, and increased irritability are hallmarks to watch for. (Refer to the “Alzheimer’s Disease in Down Syndrome” section.)

12. **B.** Many patients who have mild-to-moderate cognitive impairment are able to provide meaningful information about their medication regimens when asked in an appropriate way. (Refer to the “Patient Care Process” section.)

13. **C.** Sleep disorders are common for people who have ASD. Initially, clinicians should inquire about the patient’s activities around bedtime, to see if changes can be made to reduce stress or activation. Medications, such as melatonin, should be tried only after nonpharmacological interventions have failed. (Refer to “Pharmacologic Therapy” in the “Autism Spectrum Disorder” section, Table e93-2.)

14. **A.** Interventions for a person with ASD should be based on their functional limitations and the patient and caregivers goals and aspirations, using a multidisciplinary team to create a plan that is continually reviewed and updated as the patient matures. (Refer to “Treatment” and “Desired Outcomes” sections in the “the Autism Spectrum Disorder” section.)

15. **D.** Psychotropic medications should be used carefully for people with IDD, due to polypharmacy, atypical responses to psychotropic therapy, and the inability for a person with IDD to describe the harmful or distressing effects of psychotropic therapy other than through changes in behavior. (Refer to the “Epidemiology” section.)

Chapter e95: Acute Hyperglycemia

Paul M. Szumita; James F. Gilmore; Jennifer M. Trujillo

KEY CONCEPTS

KEY CONCEPTS

① Hyperglycemia is common among patients admitted to the hospital; at least one-third of hospitalized patients experience hyperglycemia.

② Acute hyperglycemia and hypoglycemia can lead to increases in mortality as well as complications such as surgical site infections and end-organ dysfunction.

③ Hospitalized patients are unstable, as such a patient's treatment strategies will change as the patient moves through different levels of care.

④ Insulin is the mainstay of therapy in acutely ill patients in the hospital.

⑤ The three core components of a complete insulin regimen are basal, nutritional, and correctional.

⑥ Hyperglycemic emergencies require hospitalization and are managed through a multifaceted approach of fluid resuscitation, insulin administration, and electrolyte monitoring/repletion.

INTRODUCTION

① Acute hyperglycemia is a common presentation in the ambulatory, emergency department, and inpatient hospital settings. The management of acute hyperglycemia in the emergency department and in the inpatient setting often differs from the management of diabetes in the ambulatory setting. Acute hyperglycemia is also managed differently depending on diagnosis (eg, diabetic ketoacidosis [DKA] or hyperosmolar hyperglycemic state [HHS], or acute stress hyperglycemia) and patient acuity (critically ill, acutely ill, step-down, and transitioning to outpatient). Increases in mortality and morbidity have been observed with hyperglycemia, hypoglycemia, and glycemic variability.[1–4]

② Controlling blood glucose (BG) during hospitalization has clear benefits, including improved outcomes and decreased length of stay.[4] This chapter will review the causes of dysglycemia in the hospital, as well as recommendations to manage hyperglycemia and prevent negative outcomes. Patients being admitted to the hospital may acutely pass through several phases of care, including the emergency department, general ward, and the intensive care unit (ICU). Each of these phases poses unique challenges, different goals in treatment, and different modalities of therapeutics. This chapter will evaluate medication therapy options for patients in the hospital experiencing acute hyperglycemia, as well as patients experiencing a hyperglycemic emergency such as DKA or HHS. This chapter will also cover how a multidisciplinary effort to identify, treat, and monitor glucose throughout the hospitalization is critical to achieving positive patient outcomes during the hospital stay, safely and efficiently transitioning patients home, and preventing readmission to the ICU or hospital.

EPIDEMIOLOGY

Greater than one-third of patients who are hospitalized experience hyperglycemia.[5,6] Many patients with acute hyperglycemia may not have a diagnosis of diabetes. Patients without a current diagnosis of diabetes may have stress-induced hyperglycemia or previously undiagnosed diabetes and should be evaluated for a diagnosis of diabetes. Routine monitoring of BG is the standard of care in all patients who are admitted to the hospital to identify dysglycemia. Patients with known diabetes should have a hemoglobin A1C (A1C) drawn when admitted if a result is not available from the past 2 to 3 months. Obtaining an A1C should also be done in patients with BG greater than 140 mg/dL (7.8 mmol/L) admitted to the hospital if not performed in the prior 3 months.[4] Obtaining an A1C upon admission is needed to determine whether a patient meets diagnostic criteria for diabetes, which, in turn, will dictate the discharge plan and long-term management strategy beyond the acute hyperglycemia.

ETIOLOGY/PATHOPHYSIOLOGY

Acute Hyperglycemia

Multiple mechanisms can lead to hyperglycemia in acutely ill patients. Most commonly, this may include insufficient antihyperglycemic therapy in patients with a known history of diabetes since many patients with diabetes will have non-insulin agents discontinued on admission, but not replaced with an equipotent antihyperglycemic regimen.[7] Patients in the hospital will frequently experience increases in insulin resistance in peripheral tissues, as well as increases in both hepatic and renal gluconeogenesis.[8] Acute hyperglycemia related to acute illness, commonly referred to as stress hyperglycemia, is caused by the release of the hormones norepinephrine, epinephrine, cortisol, and growth hormone and will increase inflammatory mediators leading to insulin resistance.[9] Hyperglycemia can increase pro-inflammatory cytokines, prothrombotic mediators, and increase oxidative stress.[10] External factors potentially contributing to hyperglycemia include the use of dextrose containing intravenous admixtures and maintenance fluids, medications known to increase glucose levels (glucocorticoids), and nutrition with high carbohydrate tube feedings.[7]

Hyperglycemic Emergencies

The cause of both DKA and HHS is a complex metabolic process that is the result of absolute and/or relative insulin deficiency. Episodes of DKA and HHS usually develop secondary to an underlying cause. The most frequent inciting cause of DKA and HHS is infection. Other common causes are inadequate insulin therapy (including patient non-adherence), pancreatitis, myocardial infarction, and medications. Medications that have been implicated as precipitating factors for hyperglycemic emergencies include corticosteroids, thiazide diuretics, and atypical antipsychotic agents. HHS may progress after severe dehydration in chronic illnesses where patients are experiencing decreased water intake, potentially due to being bedridden. Many patients who develop HHS have no previous diagnosis of diabetes, so the development of HHS is not recognized in a timely manner, and treatment is not initiated early. Rates of hospitalization due to DKA increased 54.9% from 2009 to 2014, a trend that is concerning given the largely preventable nature of DKA if the cause is found to be medication non-adherence.

The initiating insult can cause hyperglycemia due to increased gluconeogenesis and decreased glucose utilization by peripheral tissues, as well as an increase in counter-regulatory hormones such as glucagon. Insulin deficiency and increased hormone production will also lead to increased hepatic ketone production and lipolysis from adipose tissue, causing metabolic acidosis.

The deleterious effects of hyperglycemia are well documented in many organ systems throughout the body, and as such, it is important to address glucose status in all acutely ill patients. Persistent hyperglycemia and hypoglycemia have been associated with increased mortality in the acutely ill.

Hyperglycemia has been suggested to inhibit the function of white blood cells, leading to delayed wound healing and overall blunting of the body's immune response. Hyperglycemia can impair blood flow and cause decreases in perfusion in patients with acute coronary syndrome.[11] Derangements in BG are suggested to be associated with increased mortality and may have a contributing role to the development of ICU acquired weakness.[3,12,13]

CLINICAL PRESENTATION

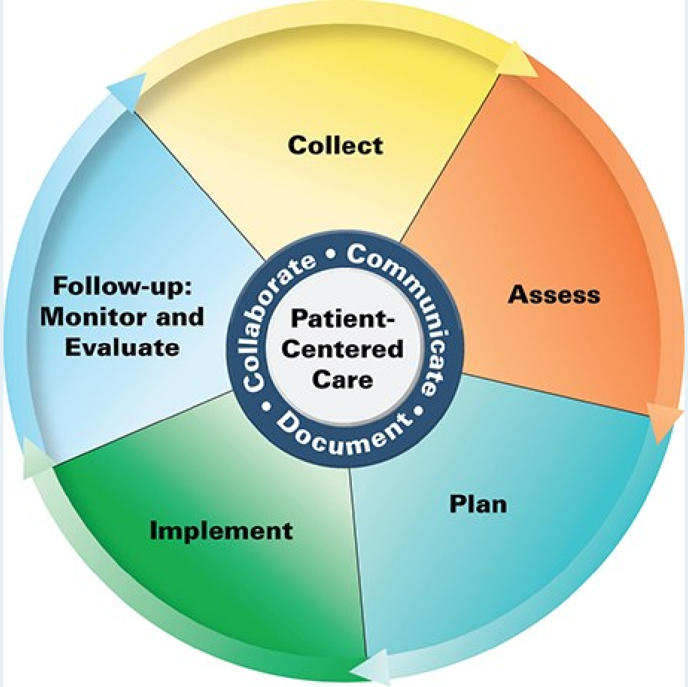
Acute hyperglycemia may present without symptoms, with non-specific symptoms, or with severe symptoms including dehydration and acid-base abnormalities symptoms. It is critical to ask the patient to provide any relevant history of medication non-adherence to help with diagnosis and explanation of the hyperglycemia.

Hypoglycemia may occur as an adverse effect of treatment and will present with symptoms generally in accordance with the degree of severity. Hypoglycemia at BG of 54 to 70 mg/dL (3.0 to 3.9 mmol/L) will generally have mild symptoms such as mood changes, while severe hypoglycemia (less than 54 mg/dL [3.0 mmol/L]) may present with severe mental status changes and unresponsiveness.[14]

DKA most often presents with uncontrolled hyperglycemia, metabolic acidosis, and an increase in ketone production. HHS will often clinically manifest with dehydration, hyperglycemia, and hyperosmolality, usually in the absence of a significant acidosis. Most patients presenting with DKA will have known or in some cases newly diagnosed type 1 diabetes (type 1 DM); however, patients with type 2 diabetes (type 2 DM) with a precipitating illness such as infection are also at risk of progressing into DKA.

PATIENT CARE PROCESS

Patient Care Process for Acute Hyperglycemia



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnancy)
- Patient medical history (personal and family) - diagnosis of diabetes
- Current medications - oral antidiabetic medications, insulin, and non-insulin injectable agents, time of the last dose

- Objective data (labs including blood glucose, A1C if not done within 90 days prior to admission)

Assess

- Presence of hyperglycemia provoking factors (infection, new corticosteroids, interruption of prehospital diabetes regimen)
- Presence of risk factors for hypoglycemia
- Dietary status (NPO, continuous tube feeds, discrete meals)
- Hemodynamic stability, patients on vasopressors or experiencing profound edema may be inappropriate for subcutaneous insulin
- Ability/willingness to self-monitor blood glucose if needed as the patient transitions to an outpatient
- Ability/willingness to self-inject insulin (if needed) as an outpatient
- Ability/willingness to pay for antidiabetic treatment options, insurance coverage of insulin pens versus vial + syringe

Plan

- Drug therapy regimen includes specific insulin(s), dose, route, frequency, and duration; (see Table e95-3)
- Monitoring parameters include efficacy (serum blood glucose as part of daily metabolic panel, point of care blood glucose testing prior to meals or standing nutritional insulin doses) and safety (eg, signs and symptoms of hypoglycemia)
- Referrals to other providers when appropriate (eg, primary care, endocrinologist, dietician)

Implement

- Best practice recommendations for the management of acute hyperglycemia given patient factors and level of acute illness (eg, emergency unit, intensive care unit, inpatient ward)
- Provide patient education regarding all elements of the treatment plan (eg, the purpose of treatment, dietary and lifestyle modification, medication administration/injection technique)
- Use motivational interviewing and coaching strategies to maximize adherence to treatment and blood glucose monitoring plan when planning to transition to outpatient

Follow-up: Monitor and Evaluate

- Blood glucose results (fasting, pre-meal), adjust insulin doses to reach goal blood glucose and avoid hypoglycemia
- Need for changes in insulin requirement given the improvement in critical illness, changing caloric intake, or tapering of corticosteroids
- A1C results every 3 months

TREATMENT

Patients Hospitalized on Antidiabetic Therapy

Many patients with a diagnosis of diabetes before hospitalization will be on an existing antidiabetic regimen. It is important to assess each patient's outpatient regimen to ensure the correct products, doses, and patient's adherence is available to healthcare providers to aid in the assessment of hyperglycemia. It may be suggested to continue patients on their outpatient regimen upon admission to the hospital. It is important to recognize that acutely ill patients are often unstable, and as such a continuation of a patient's home regimen for hyperglycemia may not be appropriate at admission.

③ The patient's home regimens may include oral and non-insulin subcutaneous agents that may cause toxicities when organ function is compromised or may not be on an institution's formulary. The core reason why antidiabetic regimens should generally be changed when in the hospital is that inpatient situations are unstable when compared to the patient's life outside the hospital. A stable regimen outside of the hospital may be too aggressive or not aggressive enough. A patient with well-controlled type 1 DM stable on an insulin pump admitted to the hospital for an elective procedure may be most appropriately managed by continuing their insulin pump. A patient with type 2 DM on multiple oral agents and admitted for the treatment of pneumonia would be better served by discontinuing their home therapy to avoid toxicities. A patient's caloric intake is likely to be different when meals are either skipped due to illness or provided via the hospital's nutrition support services which differ from the patient's usual diet.

There is no single treatment approach suitable for all hospitalized patients. Monitoring BG values closely in the hospital is crucial, and reassessing medications during each transition between levels of care. It may be appropriate to re-initiate elements of a patient's home antidiabetic regimen prior to hospital discharge as acuity decreases.

Hyperglycemia in the Noncritically Ill Hospitalized Patient

Guideline Recommendations for Nonemergent Hyperglycemia Management

Multidisciplinary guidelines play a critical role in guiding glucose management strategies for healthcare professionals in the hospital. Recommendations on glucose management in hospitalized patients are made by several professional organizations.

American Diabetes Association/American Association of Clinical Endocrinologists Consensus Statement

In 2009, the most recent consensus statement from the American Diabetes Association (ADA) and American Association of Clinical Endocrinologists (AACE) on inpatient glycemic control was released.[15] For noncritically ill hospitalized patients, the consensus statement recommends that the premeal BG target should generally be less than 140 mg/dL (7.8 mmol/L) and random BG values less than 180 mg/dL (10.0 mmol/L), provided these targets can be safely achieved. Therapeutically, they strongly discourage the use of a sliding scale insulin regimen alone. Scheduled subcutaneous administration of insulin, with basal, nutritional, and correctional components, is the preferred method for achieving and maintaining glucose control in noncritically ill hospitalized patients with good nutritional intake.

American Diabetes Association

The ADA publishes updated standards of care for diabetes annually. While the guidelines incorporate large volumes of research into their updates each year across all domains of care for patients with diabetes, recommendations specific to the management of glucose in the hospital have not substantially changed. For patients hospitalized not in the ICU, the ADA recommends insulin therapy should be initiated for treatment of persistent hyperglycemia starting at a threshold ≥180 mg/dL (10.0 mmol/L). Once insulin therapy is started, a target glucose range of 140 to 180 mg/dL (7.8 to 10.0 mmol/L) is recommended for the majority of critically ill and noncritically ill patients (Grade A Recommendation).[4]

Noninsulin Medications

There are many limitations of noninsulin therapies in hospitalized patients including absorption, drug-disease interactions, drug-drug interactions, inconsistent diet, and acute renal and hepatic injury. Oral antidiabetic medications are generally not preferred in the institutional setting for acutely ill patients, who may be experiencing decreases in absorption from their GI tract. A summary of considerations for using noninsulin antidiabetic therapies in the hospital can be found in Table e95-1. Many oral antidiabetic medications have long half-lives, making active titration during an acute hospitalization difficult. These medications will also rely on hepatic metabolism or renal excretion. Since end-organ function may be fluctuating or be impaired in acute illness, clearance of oral agents may be impaired. This accumulation can lead to increases in adverse effects such as hypoglycemia with sulfonylureas or lactic acidosis in the case of metformin. The 2021 ADA guidelines state that the safety and efficacy of noninsulin therapies in the hospital is an area of active research. This includes the potential role of glucagon-like peptide 1 receptor agonists and dipeptidyl peptidase-4 inhibitors in specific groups of hospitalized patients. The statement does not recommend any noninsulin therapies for routine use in the hospital as non-insulin agents are inappropriate in most hospitalized patients.[4]

TABLE e95-1

NonInsulin Therapies in the Hospital

Medication Type	Considerations in Hospitalized Patients
Sulfonylureas	- May lead to hypoglycemia if nutrition is interrupted or acute renal injury
Metformin	- Contraindicated in setting of decreased renal blood flow, surgery, and with use of iodinated contrast dye
Thiazolidinediones	- Long onset - Associated with edema and congestive heart failure
GLP-1 receptor agonists	- Impact mostly on postprandial glucose - Limited utility in patients not eating meals - Associated with nausea
DPP-4 inhibitors	- Limited utility in patients not eating meals as impact mostly on postprandial glucose

GLP-1: Glucagon-like peptide 1, DPP-4: Dipeptidyl-peptidase 4.

Subcutaneous Basal/Nutritional Insulin

The inpatient regimen of choice for most hospitalized noncritically ill patients with hyperglycemia or preexisting diabetes is scheduled subcutaneous (SC) insulin.[16,17] ④ The inpatient insulin regimen generally consists of the following three components: basal insulin to manage glucose between meals, nutritional (also known as prandial) insulin for meal-related nutritional BG spikes, and correctional insulin given in addition to the nutritional insulin dose in the event the patient might have premeal hyperglycemia (Table e95-2). ⑤ For most patients, the total daily dose (TDD) is split evenly with 50% of the TDD as basal insulin and 50% of the TDD as nutritional. Sliding-scale insulin alone is not recommended for glucose management in hospitalized patients.[4,18–20] The monitoring provided with a sliding scale is important information, however only utilizing a sliding scale is reactive to hyperglycemia, rather than proactive in avoiding hyperglycemia. Most insulin doses in the hospital should be accompanied by a BG check, patients with known diabetes or experiencing acute hyperglycemia without an existing diagnosis of diabetes should have BG checks before every meal if eating, and every 4 to 6 hours if not eating.[4,6,21]

TABLE e95-2

Therapeutic Options for Glycemic Control in the Medical or Stabilized Surgical Patient

	Basal Insulin	Nutritional (prandial) Insulin	Correctional (supplemental) Insulin
Place in therapy	Controls fasting and pre-meal glucose	Controls glucose from nutritional sources such as discrete meals, tube feeds, or TPN	Used to cover unexpected hyperglycemia that was not controlled by scheduled basal and nutritional insulin
Patient eating discrete meals	• Long-acting insulin once- or twice daily or • Intermediate-acting insulin (NPH) twice-daily	• Rapid-acting insulin given with a meal	• Rapid-acting insulin with meals (in addition to prandial insulin if hyperglycemic)
Patient not eating discrete meals	• Long-acting insulin once or twice-daily or • Intermediate-acting insulin (NPH) twice-daily	Not applicable	• Regular insulin every 4-6 h or • Rapid-acting insulin every 4 h
Enteral tube feeding or continuous dextrose	• Long-acting insulin once- or twice-daily or • Intermediate-acting insulin (NPH) twice-daily	• Regular insulin every 4-6 h or • Rapid-acting insulin every 4 h	• Regular insulin every 4-6 h (in addition to prandial insulin if hyperglycemic) or • Rapid-acting insulin every 4 h (in addition to prandial insulin if hyperglycemic)

When starting a new SC regimen on a treatment naïve patient, the starting estimated TDD required of SC insulin is calculated using the patient's weight. A conservative standard starting dose for an individual who has never been on insulin before is usually 0.2 to 0.7 units/kg/day.[15–18] It is best to begin at the lower end (as low as 0.2 units/kg/day) for patients at risk of hypoglycemia, such as those presenting with acute end-organ dysfunction. Doses at or above 0.7 units/kg/day should be reserved for patients with substantial risk factors for hyperglycemia, such as newly increased corticosteroids. The TDD is then divided, with one-half into the basal insulin and the other half into the nutritional insulin. Considerations in starting a new SC regimen are listed in Table e95-3.

TABLE e95-3

Initiation of Insulin Therapy on Insulin Naïve Patient

Piece of Regimen	Recommendation
Calculate starting TDD	0.2-0.4 units/kg/day - patients with hypoglycemia risk factors
	0.5-0.7 units/kg/day- standard for most patients
Adjust TDD up or down based on	Past response to insulin
	Presence of hyperglycemia-inducing risk factors, agents, stress
Basal insulin = 40%-50% of TDD	Long-acting insulin daily or twice-daily or intermediate-acting insulin twice-daily
Nutritional insulin = 50%-60% of TDD	Standing rapid-acting insulin (with discrete meals or bolus feeds) or regular insulin every 4 to 6 hours (continuous feeds)
Correctional Insulin	Insulin scale with intensity based on TDD

TDD, total daily dose.

Basal Insulin

Basal insulin refers to the patient's insulin requirements that exist regardless of the patient's caloric intake. Basal insulin should be given to patients regardless of whether they are eating or not eating. Options for basal insulin are most commonly a once-daily dose of long-acting insulin or twice daily intermediate-acting insulin NPH. Caution should be taken in patients who do not have a history of diabetes when considering initiation of long-acting basal insulin in the hospital. One retrospective analysis of surgical ICU patients without diabetes indicated an increase in the development of hypoglycemia in patients maintained with long-acting basal insulin plus sliding-scale insulin when compared to patients maintained on sliding scale insulin alone.[22] Therefore, the risks of therapy should be weighed against the potential benefits for each individual patient.

Nutritional Insulin

As discussed above, inpatient situations are often unstable, and patients can have fluctuation in their caloric intake for several reasons (NPO for the procedure, loss of feeding tube access, emesis, etc.). For these reasons, it is important to separate out nutritional insulin administration from basal insulin administration. It is important that orders are written correctly to allow for when there are acute changes in carbohydrate intake, nutritional insulin doses can be held to avoid causing episodes of hypoglycemia.

When choosing a nutritional insulin product, it is of utmost importance to distinguish the source of a patient's glucose intake and nutritional status. For patients who are on a continuous hourly rate of tube feeding or receiving total parenteral nutrition, providing a fixed dose of regular insulin every 6 hours or rapid-acting insulin every 4 hours should provide consistent coverage and avoid "stacking" of insulin doses. For patients who are eating discrete meals, or receiving bolus tube feeding, using rapid-acting insulin such as insulin aspart, insulin lispro, or insulin glulisine before meals to cover the carbohydrate intake is preferred, as the insulin analogs will offer a similar profile to the natural pancreatic insulin production in response to carbohydrate intake. Some patients may benefit from a more dynamic approach to nutritional insulin that is calculated based on the carbohydrate content of each individual meal. This is commonly referred to as "carb counting". Another strategy used by hospitals, particularly with patients who may not eat a full meal is to give the dose post-prandial (within 15 minutes after eating) depending on how much the patient ate of their meal, for example, if the patient ate only half of their meal, they would receive half of the regularly scheduled nutritional dose.

Correctional Insulin

The final piece to a successful subcutaneous insulin regimen is correctional insulin, to be administered in addition to, and at the same time as the patient's nutritional insulin. Correctional insulin is usually seen in the form of a correction or supplemental scale. Prescribers should be able to choose between different levels of the supplemental scale, based on the patient's level of insulin sensitivity, which can be determined by the patient's daily requirement of insulin or other patient characteristics such as body weight. An example of a supplemental insulin scale delivered based on scheduled insulin requirements can be found in Table e95-4.

TABLE e95-4

Example of Correctional Insulin Scales Based on Scheduled Insulin Requirement

Blood glucose (mg/dL)	Less than 40 units/day scheduled insulin"low scale" (units of insulin)	40-80 units/day scheduled insulin"medium scale" (units of insulin)	Greater than 80 units/day scheduled Insulin"high scale" (units of insulin)
150-199 (8.3 - 11.0 mmol/L)	1	1	2
200-249 (11.1 - 13.8 mmol/L)	2	3	4
250-299 (13.9 - 16.6 mmol/L)	3	5	7
300-349 (16.7 - 19.4 mmol/L)	4	7	10
Greater than 349 (19.4 mmol/L)	5	8	12

Glucose Monitoring

There are multiple methods available for glucose monitoring for patients in the hospital. Most utilized are bedside point of care testing (POCT) devices that result quickly for the bedside practitioners to act upon rather than wait for results from a central laboratory. The POCT devices usually use capillary blood from a finger stick, however venous blood or arterial blood can also be used. Variability in the glucose value will exist from each site so it is of great importance that whenever possible patients are assessed using the same source of blood to minimize this variability.

POCT monitoring is popular due to the convenience of bedside testing and the relatively fast results. POCT devices have variable accuracy, though, and the use of such instrumentation requires training and continual competency assessment of nursing and nursing support staff to ensure proper technique. The International Organization for Standardization criteria requirement for accuracy is that displayed values be within 20% of the actual BG level for all readings greater than 75 mg/dL (4.2 mmol/L).[23,24]

Blood samples collected by venipuncture, venous line, or arterial line and sent to a central laboratory are typically processed with a whole-blood analyzer or an arterial blood-gas analyzer. These methods should produce the most accurate results; however, the results can take considerably longer, limiting utility for patients when results are needed in a timely fashion, particularly around meals or if patients may be experiencing symptoms of hypoglycemia. Blood analyzers are more expensive than POCT devices; therefore, they are typically not used in at the bedside with frequency. Patients who are active in the management of their diabetes may want to self-monitor their BG while in the hospital using a home device. In these cases, the hospital should consider a policy on how these cases should be handled, and additionally require testing of BG values at the same time with a hospital-approved device.

Patients receiving insulin in the hospital should have their BG checked throughout the day. For many patients this will be driven by a whole BG reading as part of their regular basic metabolic panel of laboratory values is the morning, and throughout the day as part of their correctional scale driven based on nutritional intake. Patients eating discrete meals should have their BG checked before meals, and patients who are NPO or continuous feeds should have their BG checked every 4 to 6 hours.

Hyperglycemia in the Intensive Care Unit

Guideline Recommendations

In the critically ill population, there are several multidisciplinary organizations that have made recommendations on how BG should be managed. It is important for healthcare professionals to recognize the variability that may exist between these groups and specific guidance provided for subgroups of patients.

Society of Thoracic Surgeons

The Society of Thoracic Surgeons (STS) Practice Guideline for Blood Glucose Management During Adult Cardiac Surgery provides guidance for the management of hyperglycemia in patients undergoing cardiac surgery.[25] STS guidelines provide evidence to support targeting BG values less than 180 mg/dL (10.0 mmol/L) including reduced mortality, reduced morbidity, lowered incidence of wound infections, reduced hospital length of stay, and enhanced long-term survival. STS recommends that cardiac surgery patients with BG values greater than 180 mg/dL (10.0 mmol/L) receive intravenous insulin to maintain BG values below 180 mg/dL (10.0 mmol/L) for the duration of their ICU stay (Level A recommendation). STS also recommends that patients who will require three or more days in the ICU should have intravenous insulin infusion to keep BG values less than or equal to 150 mg/dL (8.3 mmol/L)(Level B recommendation).

American Diabetes Association/American Association of Clinical Endocrinologists Consensus Statement

For the subset of critically ill patients, it is recommended to initiate insulin therapy at a BG threshold of 180 mg/dL (10.0 mmol/L), and that a goal BG value of 140 to 180 mg/dL (7.8 to 10.0 mmol/L) is recommended for most critically ill patients. They recommend using intravenous infusions as the preferred method of delivering insulin, as well as a validated intravenous insulin protocol with demonstrated efficacy and low rates of hypoglycemia.[15]

American Diabetes Association

In the 2021 recommendations for critically ill patients, the ADA recommends the initiation of insulin therapy at a BG level of 180 mg/dL, and a goal BG range of 140 to 180 mg/dL (7.8 to 10.0 mmol/L) for the majority of critically ill patients (Grade A recommendation).[4] The guidelines concede, however, that tighter BG goals may be appropriate for selected patients if the intervention used to achieve them will not lead to increases in hypoglycemia (Grade C recommendation). The guidelines do not make a recommendation on the specific insulin infusions to be used, stating only that intravenous insulin infusions should be administered based on validated written or computerized protocols that allow for predefined adjustments in the infusion rate, accounting for glycemic fluctuations and insulin dose.

American College of Critical Care Medicine/Society of Critical Care Medicine

Further guidelines on the use of intravenous insulin in the critically ill population are offered from the American College of Critical Care Medicine (ACCM) and Society of Critical Care Medicine (SCCM) guidelines published in 2012.[26] These guidelines recommend initiation of insulin therapy when BG values are greater than 150 mg/dL (8.3 mmol/L) (level of evidence low), and that most ICU patients should be treated to a BG goal of less than 150 mg/dL (8.3 mmol/L) and absolutely less than 180 mg/dL (10.0 mmol/L) using a protocol that demonstrates low rates of hypoglycemia, suggesting that BG values less than or equal to 70 mg/dL (3.9 mmol/L) are associated with increased mortality, that even brief BG values ≤ 40 mg/dL (2.2 mmol/L) are independently associated with a greater risk of mortality (quality of evidence: low).

These guidelines weigh in on certain specific populations of patients with regards to how their glucose should be managed. The guidelines suggest for patients who have undergone trauma and are in the ICU, BG greater than or equal to 150 mg/dL (8.3 mmol/L) should trigger initiation of insulin therapy and titrated to keep BG values less than 150 mg/dL (8.3 mmol/L).[26] While less than 150 mg/dL (8.3 mmol/L) is the goal, the patient's BG should absolutely be maintained less than 180 mg/dL (10.0 mmol/L) using a protocol that achieves a low rate of hypoglycemia. This is important in trauma patients to achieve lower rates of infections and shorter stays in the ICU.

For patients experiencing certain neurologic conditions, specifically ischemic stroke, intraparenchymal hemorrhage, aneurysmal subarachnoid hemorrhage, or traumatic brain injury, the guidelines again suggest that a BG ≥ 150 mg/dL (8.3 mmol/L) serves as a trigger for initiation of insulin therapy.[26] The goal in this patient population is to keep the BG consistently less than 180 mg/dL (10.0 mmol/L) while avoiding hypoglycemia less than 100 mg/dL (5.6 mmol/L) to minimize adverse neurological outcomes.

Surviving Sepsis Campaign

More targeted recommendations are put forth in the 2021 Surviving Sepsis Campaign guideline for initiation of therapy and BG target.[27] These Guidelines recommend the initiation of a protocol for glucose management at a BG level greater than 180 mg/dL (10.0 mmol/L) in patients with sepsis, and remark that following the initiation of insulin therapy a typical target range is 144 to 180 mg/dL (8.0 to 10.0 mmol/L)(strong recommendation, moderate quality of evidence).

ASPEN (American Society for Parenteral and Enteral Nutrition)

As nutritional support is not only an important issue throughout acute illness but also a major contributor to hyperglycemia in critically ill patients, official recommendations from nutritional support and organizations have also been put forth. ASPEN in accordance with SCCM recommends a goal BG range of 140 or 150 to 180 mg/dL (7.8 or 8.3 to 10.0 mmol/L) for the general ICU population (strong recommendation), noting no clinical trial has established outcomes for different BG targets in patients receiving nutritional support.[28]

There is no clear consensus among professional organizations for goal BG in critically ill patients, or recommendations on intravenous insulin protocols to achieve specific BG targets. The recommendations put forth in these guidelines are summarized in Table e95-5. This increases the need for vigilance at the institutional level to implement and rigorously evaluate glucose management in the acutely ill population utilizing the multidisciplinary team approach.

TABLE e95-5

Summary of Recommendations of National/International Guidelines

	Goal BG in ICU	Goal BG in Non-ICU Hospitalized Patients	Definition of Hypoglycemia	Guidance on Insulin Therapy
STS[25]	Less than 180 mg/dL (10.0 mmol/L) for cardiac surgery patients in the first 24 hours of admission	• Premeal: Less than 110 mg/dL (6.1 mmol/L) • Post-prandial: Less than 180 mg/dL (10.0 mmol/L)	None provided	Before intravenous insulin infusions are discontinued, patients should be transitioned to a subcutaneous insulin schedule using institutional protocols
ADA/AACE Consensus	140-180 mg/dL (7.8 - 10.0 mmol/L)	• Premeal less than	None provided	• Use of validated insulin infusion protocols with demonstrated

Statement[15]		140 mg/dL (7.8 mmol/L) • Random less than 180 mg/dL (10.0 mmol/L)		• safety and efficacy, and with low rates of occurrence of hypoglycemia
ADA Annual Standards of Care[4]	140-180 mg/dL (7.8 - 10.0 mmol/L)	140-180 mg/dL (7.8 - 10.0 mmol/L)	• Level 1: 54- 70 mg/dL (3.0-3.9 mmol/L) • Level 2: less than 54 mg/dL (3.0 mmol/L) • Level 3: clinical event requiring assistance from another person to recover	• A regimen with basal, nutritional, and correctional is the preferred treatment for noncritically ill hospitalized patients with good nutritional intake • Avoid hypoglycemia
ACCM/SCCM[26]	Less than 150 mg, absolutely less than 180 mg/dL (10.0 mmol/L)	Not discussed	Less than 70 mg/dL (3.9 mmol/L)	Avoid hypoglycemia, monitor BG every 1-2 hours
Surviving Sepsis Campaign[27]	Typical target BG 144-180 mg/dL (8.0-10.0 mmol/L)	None provided	None provided	None provided
ASPEN[28]	140 or 150-180 mg/dL (7.8 or 8.3-10.0 mmol/L)	140 or 150-180 mg/dL (7.8 or 8.3-10.0 mmol/L)	Less than 70 mg/dL (3.9 mmol/L)	None provided

Goal BG Level Based on Diagnosis of Diabetes

Patients who carry a diagnosis of diabetes may benefit from a different goal BG level in the hospital compared to patients who do not carry the diagnosis of diabetes. It is theorized that in patients with diabetes, adaptation to a chronic hyperglycemic state may occur, and thus patients with diabetes will not benefit from tighter BG targets in the 80 to 110 mg/dL (4.4 to 6.1 mmol/L) range because a normoglycemic range for these patients may be higher. One retrospective cohort analysis evaluated 3,529 patients using the same protocol, allowing for providers to choose between 80 and 110 mg/dL (4.4 to 6.1 mmol/L) or 90 and 140 mg/dL (5.0 and 7.8 mmol/L) for a goal BG level, in 12 ICUs across eight hospitals.[29] After multivariate analysis, there was no significant difference in 30-day mortality between the groups demonstrated based on glucose target. When stratified based on diabetic status, it was demonstrated that the 90 to 140 mg/dL (5.0 to 7.8 mmol/L) glucose target was independently associated with increased risk of mortality in patients without diabetes when compared to an 80 to 110 mg/dL (4.4 to 6.1 mmol/L) target range but decreased risk of mortality in patients with diabetes.

Another retrospective analysis of 5,567 patients evaluating the relationship between preadmission A1C, glycemic metrics in the ICU, and mortality in the critically ill found that A1C values over 8% (64 mmol/mol) were associated with lower mortality in patients with mean BG values greater than or equal to 180 mg/dL (10.0 mmol/L) compared to patients with lower A1C values. Increasing mortality was seen in patients with an A1C lower than 6.5% (48 mmol/mol) who experienced increasing glucose variability compared to patients with a higher A1C.[30] These two analyses demonstrate the necessity for providers and institutions to consider how to incorporate more patient-specific factors into their standards of care for glucose management in the hospital. No multidisciplinary guideline has offered different inpatient BG goals based on the patient's diabetic status.

Intravenous Insulin Infusions

Achieving goal glucose levels and outcomes in the ICU often requires the use of an intravenous insulin protocol. Ideally a protocol with demonstrated efficacy and safety in achieving desired glucose goals without increasing risk for severe hypoglycemia.[26] There is not a gold standard intravenous insulin protocol that is widely adopted, and many institutions have had to develop their own. An institutional standardized trigger point should be set for the initiation of intravenous insulin in critically ill patients. Generally, initiation of an insulin infusion is recommended in an ICU patient with at least one of the following:

- BG greater than 180 mg/dL (10.0 mmol/L) and expected ICU stay greater than 3 days
- Known history of type 1 DM
- Unstable clinical condition (such as on corticosteroids, vasopressors, variable nutrition) and at high risk for hyperglycemia
- BG persistently elevated and not controlled with SC insulin therapy

Intravenous insulin protocols may be initiated with or without a bolus dose. If electing to use a bolus dose, the bolus and initial rate of insulin should be based on the patient's BG level. If not using a bolus dose, the initial rate of insulin should still be based upon the patient's initial BG level.

Institutions will generally have developed protocols for how to titrate an insulin infusion to achieve goal glucose level and avoid hypoglycemia. These protocols will generally require frequent input of BG values to guide nursing staff to increase or decrease the insulin being administered. These protocols are often reliant on accounting for the rate of change between the patient's previous BG levels and current, requiring a calculation to be done by the nurse administering the infusion. Electronic protocols are becoming more frequently utilized by institutions to attempt to mitigate this manual calculation as a source of human error. If electronic protocols are not readily achievable, data related to the efficacy and safety of the institution's paper-based protocol should be captured and changes to the protocol should be made as necessary to optimize outcomes for patients.[31]

Glucose Monitoring in the Intensive Care Unit

Monitoring principles in the ICU are like noncritically ill patients, although the frequency of testing is often increased in patients requiring insulin therapy. Intravenous insulin has a short half-life and will require BG tests at a minimum of every 1 to 2 hours, and more frequently if changes in how nutrition is being delivered, to prevent patients from developing hypoglycemia.

It remains vital for BG values to be collected from consistent sites for interpretation by healthcare providers. Patients receiving care in the ICU may be on vasoactive therapy or fluid overloaded causing decreases in SC blood flow. Due to this decrease, checking BG from SC sites may not accurately reflect the patient's true BG, so regular use of an arterial or venous source will help healthcare providers accurately assess and manage their patient's BG.

Continuous Glucose Monitoring

Continuous glucose monitoring (CGM) devices have become more popular. In theory, these devices would provide several advantages compared with POCT testing, especially in the ability to rapidly identify hypoglycemia. These devices are placed in a variety of sites depending on the model, ranging from arterial or venous sampling to subcutaneous or proprietary interstitial space monitoring.[32–35] Currently, there are insufficient data demonstrating improved outcomes, cost-effectiveness, or safety when using CGM devices in acutely ill patients.[4] Research on these technologies in the critically ill population continues, and a CGM coupled with an intravenous insulin protocol could lead to a paradigm shift in the management of glucose in hospitals.

Transitions of Care

Each different level of care during an acute hospitalization needs to be met with different levels of monitoring and standards for the treatment of hyperglycemia. While a patient may be on multiple oral antidiabetic mediations at home those may not be appropriate throughout their acute illness. This patient may come into the hospital via the emergency department and be managed with a combination of intravenous and subcutaneous insulin therapy. This patient then may require admission to an ICU where they will be maintained on an intravenous infusion. When the patient's acute state is recovering, they will be transitioned to subcutaneous therapy for the general ward.

When the patient leaves the hospital, if it is deemed appropriate, they may then again be placed back on their noninsulin antidiabetic agents. However, this hospitalization may be a time for the healthcare provider to revisit the home regimen and depending on many factors may have the home regimen changed. If the A1C drawn at admission is elevated, an investigation should be done to determine what has led to sub-optimal treatment. Factors the healthcare provider and the patient should discuss include medication adherence, home dietary changes, and the patient's home monitoring plan. Engaging the patient in their perceived barriers may improve their adherence and engagement going forward, slowing the progression of their disease as well as preventing complications. If the patient reports an excessive pill burden as a barrier, combination products may be available as an outpatient. If the patient reports forgetting doses, the use of a pillbox, alarm, or app may help remind patients when doses are due. If the patient reports difficulty in utilizing a vial and syringe to administer insulin, insulin pens may be a more convenient option to provide the patient when they are discharged.

Follow-up appointments with the patient's ambulatory providers are vital to check in on the medication regimens. Each of these changes introduces opportunities for error if the regimen does not match with the patient's level of care

Transition from Intravenous to SC

For patients initially managed according to an intravenous insulin infusion, a transition to a subcutaneous regimen should be considered when one of the following criteria is met:

- The patient is ready for transfer out of the ICU
- The patient has been on a stable dose of the insulin infusion for greater than 24 hours, the glucose is well controlled, and the patient is no longer critically ill
- The patient is consistently requiring doses less than 0.5 units/hr

Transitions from intravenous infusion to subcutaneous regimens can lead to the development of hypoglycemia in some patients so a thorough dosing and monitoring plan is vital.[36] To safely transition patients from intravenous to subcutaneous insulin, the healthcare provider should:

1. Determine the TDD of insulin based on the average hourly insulin infusion rate for the past 6 hours. The TDD = (average hourly insulin drip rate for past 6 hours) X 24 hours.
2. Calculate 80% of the previous TDD as the new TDD (TDD × 0.8).[37]
3. Order 50% of new calculated TDD as basal insulin, and 50% as nutritional insulin to match intake (eg, separated evenly between three meals for patients eating discrete meals)
4. Give correctional insulin scale based on TDD
5. Stop insulin drip 1 to 2 hours after the first dose of nutritional insulin or 2 to 3 hours after the first dose of basal insulin is administered.

Management of Hypoglycemia in the Hospital Setting

The ADA defines hypoglycemia as a BG level of less than 70 mg/dL (3.9 mmol/L). Both the AACE and the ADA agree that insulin therapy should be adjusted when the BG level is less than 70 mg/dL (3.9 mmol/L) and re-evaluated when levels are less than 100 mg/dL (5.6 mmol/L).[4,38] Re-evaluating insulin dosing or product selection when a level less than 100 mg/dL (5.6 mmol/L) occurs may prevent a future hypoglycemic event. Due to the negative consequences of hypoglycemia, all efforts should be made to limit the incidence of hypoglycemia. Incidence of hypoglycemia should be anticipated, and a plan put in place to systematically allow nurses to treat without delay, rather than waiting for orders from a prescriber.[11,39,40]

Hospitalized patients are at a unique risk of hypoglycemia because the nutritional status may change frequently, including the patient alternating on and off NPO status, inconsistent nutritional intake while eating, and some altered mental status. A protocolized plan is warranted to monitor for, prevent, and treat hypoglycemia. This plan should involve a clear definition of and plan to manage patients at risk of hypoglycemia in the hospital environment.

One preventive strategy is to use a glucose value as a signal to reassess insulin therapy before hypoglycemia occurs. For example, a fasting BG level of less than 100 mg/dL (5.6 mmol/L) for patients on insulin therapy can be used as a signal to systematically reassess the patient’s regimen. This type of proactive approach for the prevention of hypoglycemia should be a part of the guidelines of each institution’s protocols and guidelines.

The standing hypoglycemia management protocol/guideline should encompass the explicit route, dose, and form of glucose administration, depending on the patient’s level of cognition. Insulin infusions should be discontinued (or reduced, if the patient has type 1 DM), and glucose should be administered. Repetition of BG monitoring and administration of glucose are required until the patient is stabilized. Assessing causality and adjusting treatment is then necessary. Look for the cause of hypoglycemia and determine whether other treatment modifications are needed.

Treatment of Hyperglycemic Emergencies

The most serious and common acute complications of hyperglycemia are DKA and HHS, both of which require immediate treatment and, typically, hospitalization.[41,42] ⑥ The most recent consensus statement from the ADA on the management of DKA and HHS was published in 2009. The ADA put forth treatment strategies including monitoring, correction of fluid and electrolyte status, as well as insulin therapy for patients with DKA and HHS.

Classification of Severity

Classification of severity of episodes of DKA and HHS can be important when determining optimal treatment strategies, as well as the level of care patients will require upon admission to the hospital. Table e95-6 describes the classification of severity of DKA and HHS. The severity of DKA is classified into mild, moderate, and severe DKA based on laboratory findings. Some patients may present with a mixed picture of both DKA and HHS. Patients with mild DKA who are cognitively alert and capable of taking fluids orally may be treated under observation and sent home without admission.[43] The ADA recommends admission for patients who are experiencing plasma BG greater than 250 mg/dL (13.9 mmol/L) with an arterial pH below 7.30, a serum bicarbonate level of less than 15 mEq/L (mmol/L), and a moderate or greater level of ketones in the serum or urine.[44] Patients being admitted to the hospital with mild to moderate DKA will generally be admitted to a general ward, while patients with severe DKA should be admitted to the intensive care unit.[45]

TABLE e95-6

Classification of Severity of DKA and HHS

	DKA			HHS
	Mild	**Moderate**	**Severe**	
Arterial pH	Less than 7.30	7.00-7.24	Less than7.0	Greater than 7.3
Serum bicarbonate (mmoL/L)	15-18	10-14	Less than 10	Greater than 18
Urine ketone	1-3+	1-3+	1-3+	Trace
β-Hydroxybutyrate (mmol/L)	Greater than 1	Greater than 1	Greater than 1	Trace
Serum osmolality	Normal to elevated	Normal to elevated	Normal to elevated	Greater than 320 mOsm/kg (mmol/kg)
Anion gap (mmol/L)	Greater than 10	Greater than 12	Greater than 12	Variable

DKA, diabetic ketoacidosis; HHS, hyperglycemic hyperosmolar state.

While DKA is not a diagnosis of exclusion, other disease states can produce similar laboratory abnormalities. Alternative causes of ketoacidosis include starvation ketosis and alcoholic ketoacidosis; however, these cases will often not also present with uncontrolled hyperglycemia. A severe anion gap metabolic acidosis can present from toxic ingestions such as ethylene glycol, salicylates, and methanol. For these reasons, it is important to conduct a thorough history including previous drug use to ensure an appropriate diagnosis.

Fluids

Initially, the goal of fluid therapy should be to expand the patient's intravascular and interstitial volume since both are reduced in a patient with a hyperglycemic emergency. The resuscitation fluid of choice in a hyperglycemic emergency is 0.9% sodium chloride, initially infused at a rate of 15 to 20 mL/kg/hr. As some patients are obese and the weight-based dose may be difficult to administer in the first hour, 1 to 1.5 L during the first hour is also acceptable. Patient-specific adjustments should be considered in patients with known cardiac or renal dysfunction to avoid causing dramatic fluid overload. After the initial bolus maintenance fluid rate should be based on physiologic parameters to maintain hemodynamic stability as well as the intravascular and extravascular volume. Providers should also calculate a corrected sodium (Corrected sodium = measured sodium + 0.016 x (BG -100 mg/dL)) or when expressed in SI units (Corrected sodium = measured sodium + 0.288 x (BG -5.6 mmol/L)). If the corrected sodium is high or normal, the use of 0.45% sodium chloride at a rate of 250 to 500 mL/hr is appropriate. If the corrected sodium is low, maintenance fluid resuscitation should continue to be done with 0.9% sodium chloride. The hyperglycemia will likely resolve before the ketoacidosis has resolved, as such providers should consider adding dextrose 5% in water in DKA patients with a BG less than 200 mg/dL (11.1 mmol/L) or an anion gap less than 12 mmol/L, and HHS patients with a BG less than 300 mg/dL (16.7 mmol/L) or until osmolality is less than 315 mOsm/kg (mmol/kg) and until patients are mentally alert or receiving carbohydrates in the form of enteral nutrition. Monitoring of serum chloride is also important, as large volumes of sodium chloride-containing resuscitation fluids are often given to patients undergoing a DKA/HHS episode.[46] Excessive chloride administration can lead to a prematurely closed anion gap, complicating the assessment of the patient's acid/base status. If the anion gap closure is due to high chloride levels, and not to sufficient clearance of ketones, and fluid therapy is discontinued, patients may be at risk of having the anion gap reopen. In these patients, it may be appropriate to change to a more balanced resuscitation fluid. While the 2009 guidelines have endorsed the fluid resuscitation strategy described above, research is being published exploring the role of initial resuscitation with balanced crystalloids rather than normal saline.[47,48]

Electrolytes

Beyond sodium and chloride, electrolyte abnormalities that will need to be managed in patients experiencing a hyperglycemic emergency include potassium, bicarbonate, and phosphate.

Potassium management in a patient with DKA/HHS can prove the most complicated. Patients may experience mild-moderate hyperkalemia upon presentation. Upon initiation of fluid resuscitation, insulin therapy, and correction of the ketoacidosis, a shift towards decreased potassium will occur. To prevent the occurrence of severe hypokalemia, potassium supplementation is recommended to begin when serum potassium levels fall below 5 mEq/L (mmol/L). This can be achieved by using a potassium chloride-containing maintenance fluid. If severe hypokalemia occurs, patients may require the placement of a central venous catheter to allow for infusion of concentrated potassium chloride. If patients require greater than 10 mEq (mmol) of potassium chloride per hour, cardiac monitoring should be initiated. If patients experiencing a hyperglycemic emergency are severely hypokalemic (potassium value less than 3.3 mEq/L(mmol/L) on presentation, insulin therapy should be delayed until a potassium value greater than 3.3 mEq/L (mmol/L) is obtained.

The use of sodium bicarbonate in DKA is controversial, current recommendations only favor the addition of intravenous sodium bicarbonate in patients with severe acidosis (pH less than 6.9) who are hypotensive and not responsive to intravenous fluids.

Similar to potassium, serum phosphate levels will also decrease after the initiation of insulin therapy. There has not been any benefit on clinical outcomes displayed with phosphate supplementation of patients in DKA. Due to concern of excess phosphate supplementation causing hypocalcemia, routine phosphate supplementation is not recommended for patients with a phosphate level greater than 1.0 mmol/dL.

Insulin

Intravenous Insulin therapy is the mainstay of therapy in patients with DKA and HHS in the emergency department and ICU, though patients with an uncomplicated mild-to-moderate episode of DKA or HHS may be able to be managed safely and effectively via a subcutaneous regimen. Patient-specific factors such as hemodynamic status and etiology of DKA/HHS should be considered when selecting the route of administration for insulin, since severely ill patients may have decreased subcutaneous absorption.

An example of a weight-based intravenous insulin regimen is described in Table e95-7. Debate exists about whether to initiate therapy using an intravenous bolus of insulin. If using an intravenous insulin bolus, the dose recommended is 0.1 units/kg of actual body weight, and the initial rate of insulin should be 0.1 units/kg/hr. If therapy is not initiated using an insulin bolus, it is recommended to initiate therapy at 0.14 units/kg/hr. Hourly monitoring of BG is recommended, and strategies for adjustment of the rate of insulin infusion can be found in Table e95-7. It is important to not reduce the patient’s BG too rapidly, particularly in patients experiencing HHS as too rapid a reduction in BG may result in cerebral edema.

TABLE e95-7

Intravenous Regular Insulin Management of Hyperglycemic Emergencies

Step of Treatment	Recommendation
Initial bolus dose (optional)	0.1 units/kg
Initial rate of insulin infusion	0.1 units/kg/hr in patients who receive bolus
	0.14 units/kg/hr in patients who do not receive bolus
If BG decreases by less than 10% in the first hour	Administer intravenous bolus of 0.14 units/kg and continue the previous rate
If BG decreases by greater than 75 mg/dL/hr (4.2 mmol/L/hr)	Decrease infusion rate to 0.05 units/kg/hr
DKA: If BG is less than 250 mg/dL (13.9 mmol/L)	0.05 units/kg/hr until anion gap is less than 12 mmol/L
HHS: if BG is less than 300 mg/dL (16.7 mmol/L)	0.05 units/kg/hr until osmolality is less than 315 mOsm/kg (mmol/kg)

BG, blood glucose; DKA, diabetic ketoacidosis; HHS, hyperglycemic hyperosmolar state.

The transition from intravenous insulin to subcutaneous insulin should take place once the DKA/HHS episode has resolved. Resolution of DKA is described as BG less than 200 mg/dL (11.1 mmol/L) and two of the following: Serum bicarbonate greater than 15 mEq/L (mmol/L), venous pH greater than 7.3, and an anion gap less than 12 mmol/L. Resolution of HHS is described as BG less than 300 mg/dL (16.7 mmol/L), a plasma osmolality less than 315 mOsm/kg (mmol/kg), and the patient is mentally alert. It is critical to overlap the first dose of subcutaneous insulin with the infusion by 1 to 2 hours before discontinuation of the infusion. Patients who were on a stable regimen of insulin prior to the DKA/HHS episode may be restarted on their previous regimen if the underlying cause of the emergency has been resolved. Patients who are insulin naïve can be initiated on a weight-based subcutaneous regimen on 0.5 to 0.8 units/day, split approximately evenly between a basal insulin and a nutritional insulin. A correctional insulin scale tailored to the patient's TDD of insulin with BG monitoring multiple times daily is also critical for a complete subcutaneous regimen.

For patients with mild DKA who are determined to be appropriate candidates for subcutaneous administration of insulin, patients should receive an initial dose of a rapid-acting insulin at a dose of 0.3 units/kg, and subsequently, receive 0.2 units/kg every 2 hours. When BG is less than 250 mg/dL (13.9 mmol/L), the dose should be reduced to 0.1 units/kg every 2 hours until the patient is ready to transition to a maintenance regimen. A similar rate of ketone reduction should be expected among patients who are managed with intravenous or subcutaneous insulin, however until further research is available, subcutaneous insulin may not be ideal for patients with severe DKA, anasarca, or hemodynamic instability.

Follow-up and Diabetes Education

Consultation with an available local clinical management team, such as an endocrine or a diabetes management service should be considered for complicated DKA/HHS patients or for patients with a new diagnosis of diabetes to provide a continuity of care for when the patients go to the general ward and are eventually discharged. Diabetes education to enforce medication adherence as well as how to recognize the signs and symptoms of hypoglycemia and hyperglycemia may also be appropriate for patients who may be able to avoid progression to DKA/HHS in the future. Follow-up with existing or new diabetes outpatient providers should be ensured before discharge to prevent readmission.

Team Approach to Glucose Management in the Hospital

With insulin being a high-risk medication and the primary medication for inpatient management of hyperglycemia, implementing a safe and effective environment for glucose management in the hospital requires resources across multiple disciplines. Implementation of treatment protocols to optimize patient care outcomes and minimize adverse events, a standardized, multidisciplinary team approach should be employed.

There are two main types of dedicated glucose management teams: (1) the "Multidisciplinary steering committee" with a focus on global oversight of glucose management for an institution and (2) the best practice "clinical management team" with a focus on bedside clinical management of patient's glucose.[49]

Multidisciplinary Steering Committee

The multidisciplinary steering committee's role is to provide global oversight of the institution's development and implementation of policies, order sets, protocols, and guidelines. The goals of the multidisciplinary committee should be individualized to the needs of the institution, these goals should be established and agreed upon at the time of formation and maintained through future works. The multidisciplinary steering committee focuses on protocol development, implementation, and performance improvement.

Designated champions from each involved discipline may be necessary to implement initiatives put forth by the multidisciplinary team on a departmental basis. Disciplines that should be involved in glucose management teams include pharmacists, physicians, nursing, data analysts, and nutritionists, among others. Guidelines and protocols are essential as they have been shown to improve outcomes in BG management. A new policy, order set, protocol, or guideline may not always be the best option if existing guidance exists at the institution; however existing protocols often need to be revised as more information becomes available from internal analyses. The goal of a committee should be to provide encompassing direction without over-burdening staff with excess policies and guidelines.

The steering committee should anticipate and plan for barriers to successful implementation; as well as have a system in place to monitor for success or opportunities for improvement once the change has been implemented. A stepwise approach to process improvement is described in Table e95-8.

TABLE e95-8

Stepwise Approach to Developing and Implementing Institutional Protocols and Guidelines

Phase 1: Development	Phase 2: Implementation	Phase 3: Monitoring/continuous Quality Improvement
• Creation/identification of "physical champion" • Multidisciplinary committee • Data synthesis • Protocol drafting	• Pilot analysis: efficacy, safety, adherence • Endorsement of protocol from institutional credible bodies • Education to all clinicians • Integration with electronic documentation and clinical monitoring systems	• Periodic metric assessments • Guideline updates with current literature as available • Publication of efficacy, safety, and compliance data • Benchmarking against other institutions

Clinical Management Team

In addition to the steering committee, some healthcare systems may have a "clinical management team" performing consultative services for individual patients. The order sets, protocols, and guidelines developed by the steering committee should aid multidisciplinary providers in the management of most patients. Complex patient cases in the acute care setting may require assistance beyond what is offered by these guidelines, and in these cases, the clinical management team serves to offer expert guidance. Clinical management teams can include endocrinologists, endocrine fellows, hospitalists, nurse practitioners, physician assistants, and clinical pharmacists. In addition to bedside practice, the clinical management team can also be involved in staff education, discharge planning and counseling, and facilitating change in culture.

In addition to improvements in patient care, the clinical management service model may generate revenue if advanced practice clinicians are able to bill for consultation services. An unfortunate potential cultural shift to instituting a clinical management team for glucose management is the perception that interns and residents may be less engaged in managing glucose therapy and start to refer the uncomplicated patient to the clinical management team.

Glucose management in the inpatient setting requires a multidisciplinary team approach. The creation of a steering committee or task force focused on development, oversight, implementation, and quality assessment and improvement can standardize and coordinate glucose management measures within an institution. Clinical glucose management teams with a focus on direct patient care may also help improve patient outcomes.

Acute Hyperglycemia and Sick-Day Management in the Outpatient Setting

Acute hyperglycemia can occur in the outpatient setting for a variety of reasons, and if detected early, can often be adequately treated at home to prevent DKA or HHS and hospitalization. Acute illness, infection, or inadequate insulin therapy are primary reasons for acute hyperglycemia at home.[37] Acute self-limited illness rarely presents a major problem for patients with type 2 DM but instituting a sick day plan can avoid urgent care visits from dehydration. Type 2 DM patients should perform blood glucose monitoring more often, especially if they take medications that may cause hypoglycemia. Sick day management for patients with type 1 DM is more challenging.[50] While caloric intake generally declines when people feel sick, insulin sensitivity often decreases. Thus, patients often require greater amounts of insulin to control BG during periods of acute illness. Patients with type 1 DM should increase the frequency of blood glucose monitoring, check urine ketones, and consume 120 to 150 g of carbohydrates per day. Patients should continue their usual insulin regimen and use supplemental rapid-acting insulin based on glucose results. Basal insulin should be continued regardless of nutritional intake, while mealtime insulin use should be based on the nutritional intake of the patient. Additional insulin may be needed if ketonuria develops. Ketone testing should be done if two consecutive plasma glucose readings are above 250 mg/dL (13.9 mmol/L) or if vomiting occurs, as this may be a sign of ketosis. Sugar and electrolyte solutions, such as sports drinks, can be used to maintain hydration and provide electrolytes if there are significant GI or urinary losses. They also provide glucose to keep the patient from developing hypoglycemia. However, if the BG remains consistently elevated, the patient should abstain from sugary drinks and increase the intake of sugar-free liquids.

CONCLUSION

Acute hyperglycemia is common in hospitalized patients and presents many challenges to healthcare providers. Variations in clinical conditions, level of care, and local guidelines will all impact the management of patients experiencing dysglycemia.

SELF-ASSESSMENT QUESTIONS

1. Which of the following is a common cause of acute hyperglycemia in hospitalized patients?

   A. Anti-inflammatory mediators in acute illness

   B. Nothing by mouth (NPO) status

   C. Decreased gluconeogenesis

   D. Glucocorticoid usage

2. Which of the following is true about intravenous insulin protocols?

   A. There is a nationally accepted “gold standard” protocol

   B. Electronic intravenous insulin protocols decrease human error

   C. Paper-based protocols are preferred compared to electronic protocols

   D. The initial rate of insulin should be a fixed dose, regardless of the patient’s initial blood glucose

3. Which of the following is a reason why insulin is generally recommended for the management of acute hyperglycemia instead of non-insulin medications in the hospital setting?

A. Insulin has a lower risk of hypoglycemia compared to non-insulin medications

B. Insulin is less expensive compared to non-insulin medications

C. Insulin has a faster onset of action compared to non-insulin medications

D. Insulin is easier to dose compared to non-insulin medications

4. For most patients, when initiating SC insulin therapy in the inpatient setting, a reasonable initial total daily dose (TDD) is _________units/kg/day?

A. 0.005

B. 0.05

C. 0.5

D. 5

5. Which of the following types of subcutaneous insulin components will most patients with acute hyperglycemia in the inpatient setting require to effectively attain ADA and ACE glycemic goals while minimizing the risk of hypoglycemia?

A. Basal only

B. Prandial and sliding scale only

C. Basal, prandial, and correctional scale

D. Sliding scale only

6. Acute hyperglycemia in the intensive care unit setting, with or without the diagnosis of diabetes, is correlated with:

A. Increased length of stay

B. Increased risk of myocardial infarction

C. Increase risk of bleeding

D. Increased risk of venous thromboembolism

7. Which of the following is true about correctional insulin?

A. It can be used without basal and nutritional insulin

B. It is recommended to be used at the same time as nutritional insulin

C. It is recommended to manage diabetic ketoacidosis

D. It should not be adjusted for insulin sensitivity

8. Which of the following statements most accurately describes point-of-care glucose testing?

A. Slow results

B. Variable accuracy

C. Samples need to be sent to the lab

D. Should only be used with capillary blood

9. Per the 2009 Hyperglycemic Crises in Adult Patients with Diabetes ADA guideline, the initial dosing of insulin for patients in a hyperglycemic emergency is:

    A. 10 units IV bolus followed by 1 unit/kg/hr

    B. No bolus followed by 0.01 units/kg/hr

    C. No bolus followed by 0.14 units/kg/hr

    D. 0.1 units/kg IV bolus followed by 0.14 units/kg/hr

10. The inpatient glucose clinical management team is typically tasked with all the following **except**:

    A. Manage complex patients

    B. Educate staff

    C. Develop the glucose goal for the health system

    D. Provide consultation services for clinical teams

11. Acute hyperglycemia in the outpatient setting is often caused by all the following **except**:

    A. Exercise

    B. Acute illness

    C. Infection

    D. Inadequate anti-diabetes medication

12. Which of the following is the goal blood glucose for most patients in the intensive care unit on an insulin infusion, according to the American Diabetes Association Standards of Medical Care?

    A. 110-140 mg/dL (6.1 - 7.8 mmol/L)

    B. 140-180 mg/dL (7.8 - 10.0 mmol/L)

    C. 80-110 mg/dL (4.4 - 6.1 mmol/L)

    D. 80-180 mg/dL (4.4 - 10.0 mmol/L)

13. Which of the following blood glucose values should serve as the threshold for initiation of intravenous insulin therapy in the ICU setting?

    A. ≥80 mg/dL (4.4 mmol/L)

    B. ≥110 mg/dL (6.1 mmol/L)

    C. ≥180 mg/dL (10.0 mmol/L)

    D. ≥220 mg/dL (12.2 mmmol/L)

14. A 51-year-old female with no history of diabetes mellitus is being admitted to the hospital for community acquitted pneumonia. Her blood glucose is 246 mg/dL (13.7 mmol/L) on admission and 242 mg/dL (13.4 mmol/L) when the test is immediately repeated. Should an A1C be measured now?

    A. No, an A1C does not need to be measured in the hospital, but it should be measured at his next ambulatory care visit.

    B. Yes, to detect hyperglycemia in the hospital.

C. No, because he does not have a past medical history of diabetes.

D. Yes, to help with his inpatient insulin needs and discharge planning.

15. Which of the following is true about the management of diabetic ketoacidosis (DKA)?

A. An intravenous bolus of insulin is required for severe DKA

B. Subcutaneous insulin may be appropriate for mild DKA

C. Insulin should be started regardless of serum potassium level

D. Rapid reduction in blood glucose is the primary goal of therapy

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Corticosteroids are known to cause acute hyperglycemia in the inpatient setting and beyond. Other causes include high carbohydrate meal/tube feeds, inflammation, and increased gluconeogenesis. NPO status would be a risk for hypoglycemia. See the Acute Hyperglycemia section.
2. **B.** Electronic protocols are becoming more frequently utilized by institutions to attempt to mitigate this manual calculation as a source of human error. There is no identified "gold standard" protocol now. Paper protocols typically require manual calculations and are not preferred to electronic protocols. The initial dosing of insulin should generally be based on the most recent blood glucose value. See the Intravenous Insulin Infusions section.
3. **C.** Insulin has a more rapid glucose-lowering effect when compared to non-insulin therapies. Insulin therapy can be just as expensive if not more expensive. Despite being the preferred agent for acute hyperglycemia, the dosing of insulin can be complex and is prone to hypoglycemia. See the Non-insulin Medications section and Table e95-1.
4. **C.** A reasonable starting TDD is 0.5 units/kg/day. Therefore, for a 70-kg patient, 35 units of insulin would be an appropriate starting dose based on the current guidelines. 0.005 and 0.05 units/kg/day would generally be too low of a dose. 5 mg/kg/day would typically be an excessively high dose. See the Subcutaneous Basal/Nutritional Insulin section and Table e95-3.
5. **C.** The guidelines support an inpatient insulin regimen generally consisting of the following three components: basal insulin to manage glucose between meals, nutritional (also known as prandial) insulin for meal-related nutritional BG spikes, and correctional insulin given in addition to the nutritional insulin dose in the event the patient might have premeal hyperglycemia. These guidelines emphasize the importance of not using a sliding scale insulin regimen as the only approach. See the Subcutaneous Basal/Nutritional Insulin section and Tables e95-3 to e95-5.
6. **A.** Hyperglycemia in the ICU setting is associated with increased length of stay. Myocardial infarction, bleeding, and venous thromboembolism are not correlated with acute hyperglycemia. See the Society of Thoracic Surgeons section.
7. **B.** Correctional insulin should be given in addition to the nutritional insulin dose in the event the patient might have premeal hyperglycemia. Guidelines discourage the use of correctional insulin only or sliding scale insulin only therapy. DKA should be treated with either an insulin infusion or standing doses of basal insulin, not correctional insulin. Correctional insulin should be adjusted for insulin sensitivity. See the Subcutaneous Basal/Nutritional Insulin section and Tables e95-3 to e95-5.
8. **B.** Point of care testing (POCT) is a bedside test of blood from capillary, venous, or arterial blood with fast results; however, these devices have variable accuracy. See the Glucose Monitoring section.
9. **C.** Debate exists regarding the need for intravenous bolus and the 2009 ADA guideline allows for either a bolus of 0.1 units/kg followed by 0.1 units/kg/hr, or no bolus with an insulin infusion rate starting at 0.14 units/kg/hr; therefore, either regimen can be used at the proper dosing. See the Electrolytes and Insulin sections and Table e95-7.
10. **C.** The clinical management team may be involved in helping the multidisciplinary steering committee create the glucose goals for the health system, but the multidisciplinary steering committee would be tasked with this getting input from many stakeholders. The clinical team can manage

complex patients and be available for consolations. See the Clinical Management Team section and Table e95-8.

11. **A.** Exercise generally lowers blood glucose, whereas acute illness, infection, or inadequate insulin therapy are primary reasons for acute hyperglycemia at home. See the Acute Hyperglycemia and Sick-Day Management in the Outpatient Setting section.
12. **B.** The 2021 ADA Standards of Medical Care in Diabetes support using a goal blood glucose of 140 to 180 mg/dL (7.8 to 10.0 mmol/L) for patients on insulin therapy. See the American Diabetes Association section and Table e95-5.
13. **A.** Most guidelines for the use of an insulin infusion for the management of hyperglycemia in critically ill patients suggest for ICU patients a blood glucose value of 180 mg/dL (10.0 mmol/L) or higher should trigger the initiation of insulin therapy. Both 80 mg/dL (4.4 mmol/L) and 110 mg/dL (6.1 mmol/L) are generally considered lower than the trigger and 220 mg/dL (12.2 mmol/L) would generally too high for a trigger. See the American College of Critical Care Medicine/Society of Critical Care Medicine section.
14. **D.** The ADA Standards of Medical Care recommend that an A1C should be measured in all patients with diabetes or hyperglycemia (blood glucose higher than 140 mg/dL [10.0 mmol/L]) admitted to the hospital if not performed within the prior 3 months. The A1C can help predict inpatient insulin needs and can aid in the diagnosis of previously unrecognized diabetes and discharge planning. This patient has no history of diabetes mellitus, but he has hyperglycemia in the hospital, so an A1C should be measured now. See the Epidemiology section.
15. **B.** In mild DKA, subcutaneous insulin therapy may be an appropriate option if the proper dosing regimen is initiated. Bolus intravenous insulin may not always be necessary. Insulin therapy should be delayed if the serum potassium is less than 3.3 mEq/L (mmol/L). Rapid reduction in blood glucose may be harmful and lead to cerebral edema. See the Electrolytes and Insulin sections and Table e95-7.

Chapter e98: Pituitary Gland Disorders

Joseph K. Jordan; Amy Heck Sheehan; Kashif Munir

KEY CONCEPTS

KEY CONCEPTS

① Pharmacologic therapy for acromegaly should be considered when surgery and irradiation are contraindicated, when there is a poor likelihood of surgical success, when rapid control of symptoms is needed, or when other treatments have failed to normalize growth hormone (GH) and insulin-like growth factor-1 (IGF-1) serum concentrations.

② Pharmacotherapy for acromegaly using dopamine agonists has several advantages including oral administration and lower cost when compared to somatostatin analogs and pegvisomant. However, dopamine agonists effectively normalize IGF-1 serum concentrations in only 10% to 30% of patients. Therefore, somatostatin analogs remain the mainstay of therapy.

③ Blood glucose concentrations should be monitored frequently in the early stages of somatostatin analog therapy, especially when using pasireotide.

④ Pegvisomant appears to be the most effective agent for normalizing IGF-1 serum concentrations.

⑤ Recombinant growth hormone (GH) is currently considered the drug of choice for the treatment of children with growth hormone–deficient short stature. Prompt diagnosis of growth hormone deficiency (GHD) and initiation of replacement therapy with recombinant GH is crucial for optimizing final adult heights.

⑥ All GH products are equally effective. The recommended initial dose for treatment of GHD short stature in children is 0.16 to 0.24 mg/kg/wk.

⑦ Pharmacologic agents that antagonize dopamine or increase the release of prolactin can induce hyperprolactinemia. Discontinuation of the offending medication and initiation of an appropriate therapeutic alternative usually normalizes serum prolactin concentrations.

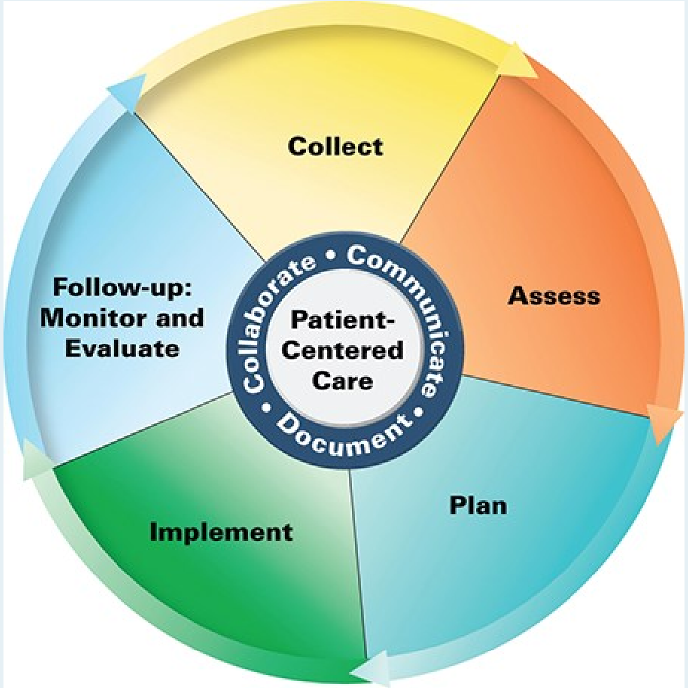
⑧ Cabergoline is more effective than bromocriptine for the medical management of prolactinomas and offers the advantage of less-frequent dosing and fewer adverse effects.

⑨ Although currently available data do not suggest that cabergoline has significant teratogenic potential, cabergoline is not recommended for use during pregnancy. Patients receiving cabergoline or bromocriptine who plan to become pregnant should discontinue the medication as soon as pregnancy is detected.

⑩ Pharmacologic treatment of panhypopituitarism includes the use of glucocorticoids, thyroid hormone, sex steroids, and recombinant GH, when appropriate, as lifelong replacement therapies.

PATIENT CARE PROCESS

Patient Care Process for Hyperprolactinemia



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnancy status)
- Patient history (past medical, menstrual cycle, family medical history)
- Social history (stress level, physical activity, dietary habits)
- Current medications including prescription, non-prescription, and herbal products
- Objective data
- Labs (eg, prolactin, macroprolactin, serum β-HCG, FSH, TSH, free T4, AST, ALT, BUN, and SCr)
    - DXA T-score of the lumbar spine
    - MRI of the pituitary gland
    - Objective confirmation of signs (see Table e98-5)

Assess

- Presence of symptoms related to local effects of prolactinoma (see Table e98-5)
- Presence of medications likely to impact prolactin levels (see Table e98-4)
- Emotional status (ie, presence of stress)
- Patient’s desire to become pregnant in the future

Plan*

- If drug-induced, discontinuation of offending medication and initiation of therapeutic alternative
- If not drug-induced, treat with a dopamine agonist, if appropriate

- Consider sex hormone replacement therapy if clinically appropriate
- Monitoring parameters including efficacy (eg, prolactin, gonadal function, tumor size, galactorrhea) and safety (bromocriptine: central nervous system [CNS] and gastrointestinal [GI] adverse effects, cabergoline: CNS and GI adverse effects, blood pressure, and cardiac valvular function, if appropriate)
- Patient education (eg, the purpose of treatment, lifestyle modification, risks and benefits of invasive procedures, drug-specific side effects, medication administration techniques, discontinue treatment if pregnancy detected)
- Self-monitoring for regularity of menstrual cycle in women and libido in men
- Referrals to other providers when appropriate

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies (eg, dose chart or pillbox) to maximize adherence
- Schedule follow-up (eg, prolactin levels to titrate dosing, adherence assessment, side effect assessment, repeat imaging)

Follow-Up: Monitor and Evaluate

- Prolactin levels (initially monitor every 3-4 weeks and 6-12 months once normalized)
- Gonadal function, bone loss, tumor size, and visual defects
- Presence of medication-specific adverse effects
- Patient adherence to treatment plan using multiple sources of information
- Pregnancy status
- Reevaluate the role of dopamine agonist therapy after 2 years of treatment in the absence of visible tumor

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Create a diagram of anterior pituitary hormones, noting the upstream signals (ie, hypothalamic-releasing or inhibiting hormones) and downstream targets of the hormones secreted by the anterior pituitary. When applicable, note inhibitory or excitatory feedback mechanisms in this process.

INTRODUCTION

It wasn't until the 1950s that the physiologic importance of pituitary hormones was understood and the neurohormonal regulation of the pituitary by the hypothalamus described.[1] The pituitary gland plays an essential role in homeostasis, and for this reason, it is often referred to as the *master gland.* The hypothalamus and the pituitary gland are closely connected, and together they provide a means of communication between the brain and many of the body's endocrine organs. The hypothalamus uses input from the central nervous system and metabolic signals from the body to control the secretion of pituitary hormones that regulate growth, thyroid function, adrenal activity, reproduction, lactation, and fluid balance.

ANATOMY AND PHYSIOLOGY

The hypothalamus (Fig. e98-1) is a small region at the base of the brain that receives autonomic nervous input from different areas of the body to regulate limbic functions, food and water intake, body temperature, cardiovascular function, respiratory function, and diurnal rhythms. In addition, the hypothalamus controls the release of hormones from the anterior and posterior regions of the pituitary gland. Neurons in the hypothalamus produce vasopressin and oxytocin and make many hormone-releasing factors that stimulate or inhibit the release of trophic hormones from the anterior pituitary that subsequently stimulate endocrine tissues to grow and release hormones. At the base of the hypothalamus, a projection known as the *median eminence* is rich with nerve axons and blood vessels and provides both chemical and physical connections between the hypothalamus and the pituitary gland.

FIGURE e98-1

Pituitary gland.

The pituitary gland, also referred to as the *hypophysis*, is located at the base of the brain in a cavity of the sphenoid bone known as the *sella turcica*. The pituitary is separated from the brain by an extension of the dura mater known as the *diaphragma sellae*. The pituitary is a very small gland, weighing between 0.4 and 1 g in adults. It is divided into two distinct regions: the anterior lobe, or adenohypophysis, and the posterior lobe, or the neurohypophysis (see Fig. e98-1).

The posterior pituitary gland secretes two major hormones: oxytocin and vasopressin (antidiuretic hormone) (Table e98-1). Oxytocin release from the posterior pituitary causes contraction of the smooth muscles in the breast during lactation. It also plays a role in uterine contraction during parturition. Vasopressin is essential for proper fluid balance and acts on the renal collecting ducts to conserve water. Oxytocin and vasopressin are synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. The posterior pituitary gland contains the terminal nerve endings of these two nuclei as well as specialized secretory granules that release hormones in response to appropriate signals. Loss of anterior pituitary function does not typically affect the release of vasopressin or oxytocin because these hormones are synthesized in the hypothalamus.

TABLE e98-1

Pituitary Hormones

Hormone	Stimulated by	Inhibited by	Physiologic Effects
Posterior Pituitary Hormones			
Vasopressin (ADH)	• Hyperosmolality • Hypovolemia • Volume depletion	• Hypervolemia • Hypoosmolality	• Acts on renal collecting ducts to prevent diuresis • Vasoconstriction
Oxytocin	• Parturition • Suckling		• Uterine contraction • Milk ejection
Anterior Pituitary Hormones			
Growth Hormone (GH)	*Physiologic*	*Physiologic*	
	• GH-releasing hormone Ghrelin • ADH • GABA • Norepinephrine • Dopamine • Serotonin • Estrogen • Sleep • Stress • Exercise	• Somatostatin • Elevated IGF-1 • Growth hormone • Progesterone • Glucocorticoids • Postprandial hyperglycemia • Elevated free fatty acids	• Stimulates IGF-I production • IGF-I and GH promote growth in all body tissues
	Pharmacologic	*Pharmacologic*	
	• α-Adrenergic agonists (eg, clonidine) • β-Adrenergic antagonists (eg, propranolol) • Dopamine agonists (eg, bromocriptine) in healthy individuals • GABA agonists (eg, muscimol)	• Dopamine antagonists (eg, phenothiazines) • α-Adrenergic antagonists (eg, phentolamine) • β-Adrenergic agonists (eg, isoproterenol) • Serotonin antagonists (eg, methysergide)	
Prolactin	*Physiologic*	*Physiologic*	
	• TRH • VIP • Estrogen • Serotonin • Histamine • Endogenous opioids • Pregnancy and nursing	• Dopamine • GABA	Lactation

	Pharmacologic	*Pharmacologic*	
	• Dopamine antagonists (eg, phenothiazines, haloperidol, methyldopa) • Opiates • Estrogens • H_2-antagonists (eg, cimetidine) • MAO inhibitors	Dopamine agonists (eg, L-dopa, bromocriptine, pergolide, cabergoline)	
Adrenocorticotropic Hormone (ACTH)	• CRH • AVP	• Elevated cortisol • Dopamine agonists • Somatostatin analog (eg, pasireotide)	• Glucocorticoid effects • Pigmentation
Thyroid-Stimulating Hormone (TSH)	• TRH • Estrogens • Norepinephrine • Serotonin	• Thyroxine • Triiodothyronine • Somatostatin • Glucocorticoids • Dopamine	Iodine uptake and thyroid hormone synthesis
Luteinizing Hormone (LH)	*Physiologic*	*Physiologic*	
	GnRH (pulsatile)	Fasting	Ovulation
	Pharmacologic	*Pharmacologic*	Maintains corpus luteum Stimulates testosterone production
	Clomiphene	• Estrogen Testosterone • GnRH (tonic, leuprolide)	
	Physiologic	*Physiologic*	
Follicle-Stimulating Hormone (FSH)	• GnRH (pulsatile) • Menopause • Ovarian disorders	• Estradiol • Inhibin • Fasting	• Ovarian follicle development • Stimulates estradiol and progesterone • Spermatogenesis
	Pharmacologic	*Pharmacologic*	
	Clomiphene	GnRH (tonic, leuprolide)	

ADH, antidiuretic hormone; AVP, arginine-vasopressin, CRH, corticotropin-releasing hormone; GABA, γ-aminobutyric acid; GnRH, gonadotropin-releasing hormone; IGF-1, insulin-like growth factor-1; MAO, monoamine oxidase; TRH, thyrotropin-releasing hormone; VIP, vasoactive intestinal peptide.

Data from References [2–4].

Unlike the posterior pituitary, the release of anterior pituitary hormones is not regulated by direct nerve stimulation but rather is controlled by specific hypothalamic-releasing and inhibitory hormones. The median eminence of the hypothalamus contains a large number of capillaries that converge to form a network of veins known as the *hypothalamic-hypophyseal portal circulation*. Inhibiting and releasing hormones synthesized in the neurons of the hypothalamus reach the anterior pituitary via the hypothalamic-hypophyseal portal vessels to control the release of anterior pituitary hormones. Although there is a direct arterial blood supply to the anterior pituitary lobe, the hypothalamic-hypophyseal portal vessels provide the primary blood supply (see Fig. e98-1). In contrast to the posterior pituitary, the anterior pituitary lobe is highly vascular and has the highest rate of organ blood flow in the body.

The specialized secretory cells of the anterior pituitary lobe secrete six major polypeptide hormones (see Table e98-1). These include growth hormone (GH) or somatotropin, adrenocorticotropic hormone (ACTH) or corticotropin, thyroid-stimulating hormone (TSH) or thyrotropin, prolactin, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The release of these hormones is regulated primarily by hypothalamic-releasing and inhibiting hormones. Thyrotropin-releasing hormone (TRH) stimulates the anterior pituitary to release TSH and prolactin; corticotropin-releasing hormone (CRH) stimulates the anterior pituitary to release ACTH; growth hormone-releasing hormone (GHRH) stimulates the anterior pituitary to release GH; and gonadotropin-releasing hormone (GnRH) stimulates the anterior pituitary to release LH and FSH. Hypothalamic release of somatostatin inhibits the release of GH, and hypothalamic release of dopamine (aka prolactin inhibitory hormone) inhibits prolactin secretion. Prolactin differs from the other anterior lobe hormones in that an inhibiting factor, rather than a stimulating factor, is primarily responsible for controlling its secretion. In the absence of hypothalamic input, prolactin is produced in excess, whereas other anterior pituitary hormones become deficient. The physiologic regulation and action of posterior and anterior pituitary hormones are summarized in Table e98-1.[2–4]

Destruction of the pituitary gland may result in secondary hypothyroidism, hypogonadism, adrenal insufficiency, GH deficiency, and hypoprolactinemia. The formation of certain types of pituitary tumors may result in pituitary hormone excess. Pituitary tumors may physically compress the pituitary and prevent the release of hypothalamic factors that regulate pituitary hormones.

In this chapter, the pathophysiology and the role of pharmacotherapy in the treatment of acromegaly, short stature, hyperprolactinemia, and panhypopituitarism are discussed.

GROWTH HORMONE

GH has direct anti-insulin effects on lipid and carbohydrate metabolism. GH decreases the utilization of glucose by peripheral tissues, increases lipolysis, and increases muscle mass. GH also stimulates gluconeogenesis in hepatocytes, impairs tissue glucose uptake, diminishes insulin-receptor sensitivity, and impairs post-receptor insulin action. The growth-promoting effects of GH are primarily mediated by insulin-like growth factors (IGFs), also known as *somatomedins*. GH stimulates the formation of IGF-1 in the liver as well as in other peripheral tissues. This anabolic peptide acts as a direct stimulator of cell proliferation and growth. There are two types of IGFs: IGF-1 and IGF-2. IGF-1 regulates growth to some extent before, and largely after, birth. In contrast, IGF-2 is thought to primarily regulate growth in utero.[5] GH is secreted by the anterior pituitary in a pulsatile fashion, with several short bursts that occur mostly at night. Because of the short half-life of GH in the plasma (~30 minutes), measurements of circulating GH concentrations throughout the waking hours usually are very low or undetectable. Daytime GH pulses are most likely to occur after meals, following exercise, or during periods of stress. The greatest amount of GH secretion occurs during the night within the first 1 to 2 hours of slow-wave sleep (stage III or IV). Secretion of GH is lowest during infancy, increases slightly during childhood, reaches its peak during adolescence, and then begins to gradually decline during the middle-age years.[3]

ACROMEGALY

Acromegaly is a pathologic condition characterized by excessive production of GH. This is a rare disorder with prevalence ranging between 2.8 and 13.7 cases per 100,000 and incidence rates ranging between 0.2 and 1.1 cases per 100,000 people.[6] Gigantism, which is rarer than acromegaly, is the excess secretion of GH prior to epiphyseal closure in children.[7] Patients diagnosed with acromegaly have a two- to threefold increase in mortality, usually related to cardiovascular, respiratory, or neoplastic disease.[7-10] Most patients are middle-aged at the time of diagnosis, and this disorder does not appear to affect one sex to a greater extent than the other.[6] The most common cause of excess GH secretion in acromegaly is a GH-secreting pituitary adenoma, accounting for over 95% of all cases.[7] Rarely, acromegaly is caused by ectopic GH-secreting adenomas, GH cell hyperplasia, excess GHRH secretion, or is a manifestation of multiple endocrine neoplasia syndrome type 1, McCune–Albright syndrome, or the Carney complex, all very rare hypersecretory endocrinopathies.[7–9]

The clinical signs and symptoms of acromegaly develop gradually over an extended period of time. The changes in physical appearance caused by GH excess are slow and subtle to develop. Thus, most patients are not diagnosed with acromegaly until 7 to 10 years after the presumed onset of excessive GH secretion.[9] Excessive secretion of GH and IGF-1 adversely affects several organ systems. Almost all patients with acromegaly will present with physical signs and symptoms of soft-tissue overgrowth. Table e98-2 summarizes the classic clinical presentation of patients with acromegaly.[7–9] Some patients with acromegaly present with only a few of these classic signs and symptoms, making recognition of this disease extremely difficult.

TABLE e98-2

Clinical Presentation of Acromegaly

General

The patient will experience slow development of soft-tissue overgrowth affecting many body systems. Signs and symptoms may gradually progress over many years.

Symptoms

The patient may complain of symptoms related to local effects of the GH-secreting tumor, such as headache and visual disturbances. Other symptoms related to elevated GH and IGF-1 concentrations include excessive sweating, neuropathies, joint pain, and paresthesias.

Signs

The patient may exhibit coarsening of facial features, increased hand volume, increased ring size, increased shoe size, an enlarged tongue, and various dermatologic conditions.

Laboratory tests

The patient’s GH concentration will be more than 1 mcg/L (45 pmol/L) following an OGTT, and IGF-1 serum concentrations will be elevated. Glucose intolerance may be present in up to 50% of patients.

Common Comorbid Conditions

- Cardiovascular diseases such as hypertension, coronary heart disease, cardiomyopathy, and left ventricular hypertrophy are common in patients with acromegaly.
- Osteoarthritis and joint damage develop in up to 90% of acromegalic patients.
- Respiratory disorders and sleep apnea occur in up to 60% of acromegalic patients.
- Type 2 diabetes develops in approximately 25% of acromegalic patients.
- Patients with acromegaly may be at higher risk of developing esophageal, colon, and stomach cancer.

OGTT, oral glucose tolerance test.

Data from References [7–9].

The diagnosis of acromegaly is based on a combination of diagnostic tests and clinical signs and symptoms. Random measures of plasma GH levels are not dependable because of the pulsatile pattern of release. However, some clinicians exclude the diagnosis of acromegaly in the presence of a random GH below 0.4 mcg/L (18 pmol/L) and IGF-1 that is normal for age and sex.[7–9] The oral glucose tolerance test (OGTT) is commonly used as an important diagnostic tool. Postprandial hyperglycemia inhibits the secretion of GH for at least 1 to 2 hours. Therefore, an oral glucose load would be expected to suppress GH concentrations. However, patients with acromegaly continue to secrete GH during the OGTT. Because GH stimulates the production of IGF-1, serum IGF-1 concentration is often measured as the initial screening test in the diagnosis of acromegaly. Circulating IGF-1 is cleared from the body at a much slower rate than is GH, and measurements can be collected at any time of the day to identify patients with GH excess.[7–9] Current criteria for the diagnosis of acromegaly include failure of GH suppression to less than 1 mcg/L (45 pmol/L) following an OGTT in the presence of elevated IGF-1 serum concentrations (strong recommendation, moderate quality of evidence).[7,8,11] With the development of more sensitive GH and IGF-1 assays, the American Association of Clinical Endocrinologists (AACE) suggests lowering the cutoff for GH suppression to less than 0.4 mcg/L (18 pmol/L), although other groups still support a cutoff of less than 1 mcg/L based on concerns of requisite sensitivity of many assays.[7,8,11] Insulin-like growth factor 1 binding protein 3 (IGFBP-3) is positively regulated by GH and binds to circulating IGF-1 with high affinity. In the future, this test may prove useful for monitoring the response to therapy but AACE does not currently recommend IGFBP-3 measurements to guide treatment decisions.[8] Computed tomography and magnetic resonance imaging (MRI) of the pituitary are important diagnostic tests to confirm the presence of a pituitary adenoma.[7,8,11]

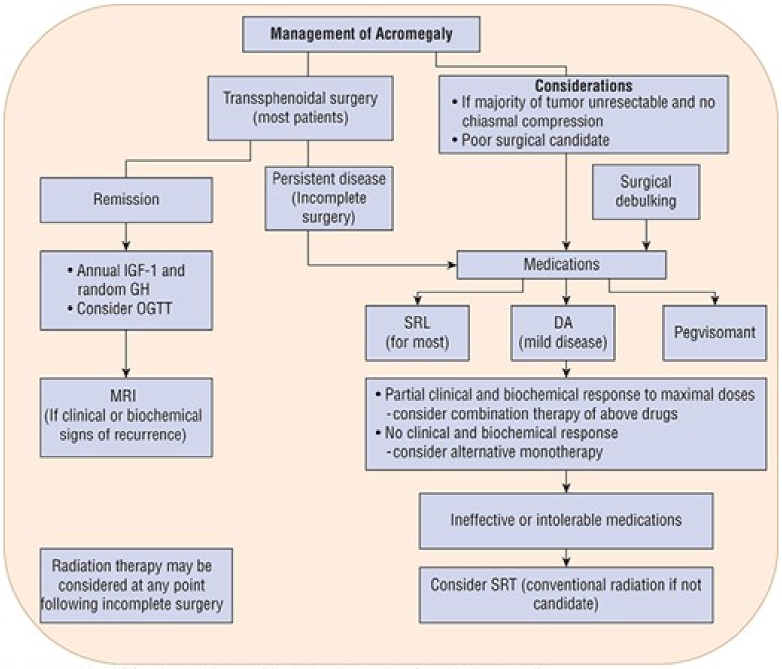
Treatment

The primary treatment goals for patients diagnosed with acromegaly are to reduce GH and IGF-1 concentrations, improve the clinical signs and symptoms of the disease, and decrease mortality.[7,8,11-14] Many clinicians define biochemical control of acromegaly as suppression of GH concentrations to less than 1 mcg/L (45 pmol/L) after a standard OGTT in the presence of normal IGF-1 serum concentrations. However, some experts have proposed a lower cutoff GH value of 0.4 mcg/L (18 pmol/L) due to the availability of more sensitive test methods.[12] The treatment of choice for most patients with acromegaly is transsphenoidal surgical resection of the GH-secreting adenoma (strong recommendation, moderate quality evidence).[7,8,11-13] Postsurgical cure rates have been reported to range from 50% to 90%, depending on the type of adenoma and the expertise of the neurosurgeon.[7,8,13] Complications of transsphenoidal surgery are relatively infrequent and include cerebrospinal fluid leak, meningitis, arachnoiditis, diabetes insipidus, and pituitary failure.[8] For patients who are poor surgical candidates, those who have not responded to surgical or medical interventions, or others who refuse surgical or medical treatment, radiation therapy may be considered. However, radiation therapy may require several years before the symptoms of acromegaly are relieved.

Because neither radiation therapy nor surgery will cure all patients with acromegaly, adjuvant drug therapy is often needed to control symptoms.[7,8,11,12] Figure e98-2 shows a treatment algorithm for the management of acromegaly.[7,8]

FIGURE e98-2

Treatment algorithm for acromegaly. (DA, dopamine agonist; SRL, somatostatin analog; SRT, stereotactic radiotherapy) (*Reprinted, with permission, from Katznelson L, Laws ER Jr, Melmed S, et al. Acromegaly: An Endocrine Society clinical practice guideline. J Clin Endocrinol Metab. 2014;99:3933–3951. Copyright 2014, The Endocrine Society.*)



Management of Acromegaly
Transsphenoidal surgery (most patients)
Considerations
• If majority of tumor unresectable and no chiasmal compression
• Poor surgical candidate
Remission
Persistent disease (Incomplete surgery)
Surgical debulking
• Annual IGF-1 and random GH
• Consider OGTT
Medications
SRL (for most)
DA (mild disease)
Pegvisomant
MRI (If clinical or biochemical signs of recurrence)
• Partial clinical and biochemical response to maximal doses -consider combination therapy of above drugs
• No clinical and biochemical response -consider alternative monotherapy
Ineffective or intolerable medications
Radiation therapy may be considered at any point following incomplete surgery
Consider SRT (conventional radiation if not candidate)

Pharmacologic Therapy

① Drug therapy should be considered primary therapy for patients with acromegaly who prefer medical therapy, are poor surgical candidates, or when there is a poor likelihood of surgical success. In addition, drug therapy should be considered as adjunctive therapy in the presence of persistent disease after surgery (strong recommendation, high-quality evidence).[7,8] The most common pharmacologic treatment options include dopamine agonists, somatostatin analogs, and the GH-receptor antagonist pegvisomant. Dopamine agonists such as bromocriptine and cabergoline are effective in a small subset of patients. Their principal advantages are oral administration and lower cost. Somatostatin analogs are more effective than dopamine agonists, reducing GH concentrations and normalizing IGF-1 in approximately 50% to 60% of patients. Pegvisomant, a GH-receptor antagonist, is highly effective in normalizing IGF-1 concentrations in up to 97% of patients in the first year and in 60% over 5 years.

Dopamine Agonists

② In normal healthy adults, dopamine agonists cause an increase in GH production. However, when these agents are given to patients with acromegaly, there is a paradoxical decrease in GH production. The greatest clinical experience with the use of dopamine agonists in acromegaly has been with bromocriptine or cabergoline. Other agents such as pergolide, quinagolide, and lisuride also have been used but are not available in the United States. Bromocriptine and cabergoline are semisynthetic ergot alkaloids that act as dopamine-receptor agonists. Most trials assessing the efficacy of bromocriptine in the treatment of acromegaly were conducted in the 1970s and early 1980s and determined that bromocriptine was effective in suppressing serum GH levels to less than 5 mcg/L (225 pmol/L) in approximately 20% of patients.[15] While only 10% of patients experience a normalization of IGF-1 concentrations with bromocriptine therapy, more than 50% of patients treated with bromocriptine experience improvement in symptoms of acromegaly.[8,15] Cabergoline is used more commonly than bromocriptine.[8] A meta-analysis of 15 studies concluded that cabergoline as monotherapy was effective in normalizing IGF-1 levels in 34% of patients and resulted in normalization of IGF-1 levels in 52% of patients when added to a somatostatin analog in those unresponsive to somatostatin analog monotherapy.[16]

In the United States, bromocriptine is commercially available as 0.8- and 2.5-mg oral tablets and 5-mg oral capsules. The 0.8-mg tablet is only approved for adjunctive therapy in type 2 diabetes mellitus. In acromegalic patients, significant reductions in GH concentrations are observed within 1 to 2 hours of oral dosing. This effect persists for at least 4 to 5 hours. An overall clinical response in acromegalic patients typically occurs after 4 to 8 weeks of continuous bromocriptine therapy. For treatment of acromegaly, bromocriptine is initiated at a dose of 1.25 mg (1/2 of a 2.5-mg tablet) at bedtime and is increased by 1.25-mg increments every 3 to 4 days as needed. Doses as high as 86 mg/day have been used for the treatment of acromegaly, but clinical studies have shown that dosages more than 20 to 30 mg daily do not offer additional benefits in the suppression of GH. When used for the treatment of acromegaly, the duration of action of bromocriptine is shorter than that for the treatment of hyperprolactinemia. Therefore, the total daily dose of bromocriptine should be divided into three or four doses.

Cabergoline is commercially available as 0.5-mg tablets. Use in acromegaly is considered off-label. Dosing is typically initiated at 0.5 mg twice weekly and increased as needed to 0.5 mg every other day. Doses up to 7 mg/wk (0.5 mg twice daily) have been used in clinical trials.

The most common adverse effects of dopamine agonist therapy include CNS symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. GI effects such as nausea, abdominal pain, or diarrhea also are very common. Some patients may need to take dopamine agonists with food to decrease the incidence of adverse GI effects. Most adverse effects are seen early in the course of therapy and tend to decrease with continued treatment.[8,15] Dopamine agonists may cause the thickening of bronchial secretions and nasal congestion. Rare cases of psychiatric disturbances, pleural diseases, and an erythromelalgic syndrome (painful paroxysmal dilation of the blood vessels in the skin of the feet and lower extremities) have been reported with dopamine agonist use. These conditions appear to be associated with higher doses and prolonged duration of therapy.[8,15]

Dopamine agonists are not FDA-approved for use during pregnancy. However, surveillance of women who took dopamine agonists throughout pregnancy does not suggest that dopamine agonists are associated with an increased risk for birth defects.[17] If a woman becomes pregnant while taking dopamine agonists, the risks and benefits of therapy should be discussed with the patient. In most cases, the benefits of successful therapy outweigh the risks, and dopamine agonist therapy should be continued if symptoms have improved and GH concentrations have been reduced.

Given the potential cost advantages and convenience of oral administration, dopamine agonists are often considered for treatment of acromegaly prior to initiation of somatostatin analogs. The Endocrine Society guidelines suggest a trial of a dopamine agonist in acromegalic patients with mild signs and symptoms and modest elevations in serum IGF-1 (weak recommendation, low-quality evidence).[7] However, long-acting somatostatin analogs are considered a more attractive first-line treatment option for acromegaly.

Somatostatin Analogs

Octreotide, lanreotide, and pasireotide are long-acting somatostatin analogs that are more potent in inhibiting GH secretion than endogenous somatostatin.[18] The Endocrine Society suggests somatostatin analogs as initial adjuvant medical therapy in patients with significant disease (weak recommendation, low-quality evidence) and as primary therapy in patients who cannot be cured by surgery or are poor surgical candidates (weak recommendation, moderate-quality evidence).[7] These agents also suppress the LH response to GnRH; decrease splanchnic blood flow; and inhibit secretion of insulin, vasoactive intestinal peptide (VIP), gastrin, secretin, motilin, serotonin, and pancreatic polypeptide. Pasireotide is a somatostatin analog that has a broader affinity for somatostatin receptor subtypes than octreotide or lanreotide, and this may result in greater GH inhibition. Pasireotide is also effective for octreotide or lanreotide-resistant adenomas.[18]

Octreotide (Sandostatin) injection is commercially available in the United States for subcutaneous or IV administration. A long-acting intramuscular formulation of octreotide (Sandostatin LAR) is available for monthly administration. An oral formulation of octreotide (Mycapssa) is also available for those who respond to and tolerate injectable octreotide or lanreotide.[19] In addition to the treatment of acromegaly, octreotide has many other therapeutic uses, including the treatment of carcinoid tumors, vasoactive intestinal peptide-secreting tumors (VIPomas), GI fistulas, variceal bleeding, diarrheal states, and irritable bowel syndrome.

The efficacy of octreotide for the treatment of acromegaly was initially determined by two major multicenter trials.[20,21] These studies demonstrated that drug therapy with octreotide suppresses mean serum GH concentrations to less than 5 mcg/L (225 pmol/L) and normalizes serum IGF-1 concentrations in 50% to 60% of patients, and reduces the clinical signs and symptoms of acromegaly. In a 6-month multicenter trial, 70% of patients experienced significant relief of headaches.[21] In some patients, relief of headache symptoms occurred within minutes of octreotide administration. In addition, middle-finger circumference was reduced significantly, and 50% to 75% of patients experienced an improvement in symptoms of excessive perspiration, fatigue, joint pain, and cystic acne. Long-term follow-up of patients with acromegaly treated with octreotide LAR for up to 9 years showed therapy to be safe and effective.[22] Octreotide also has been shown to improve the cardiovascular manifestations of acromegaly and to halt pituitary tumor growth, with some patients experiencing tumor regression.[23] Shrinkage of pituitary tumor mass occurs in approximately 50% of patients.[24]

The pharmacodynamic effects of long-acting octreotide are similar to those of subcutaneously administered octreotide. Single monthly doses of long-acting octreotide have been shown to be at least as effective as daily doses of subcutaneous octreotide administered in divided doses three times daily in normalizing IGF-1 levels and maintaining suppression of mean serum GH concentrations.[25] Trials evaluating the efficacy of long-acting octreotide in patients who previously responded to subcutaneously administered octreotide have reported sustained suppression of GH concentrations to less than 5 mcg/L (225 pmol/L) and normalization of IGF-1 in patients following 1 year of therapy.[25] Trials evaluating oral octreotide in patients who responded to injectable octreotide or lanreotide found that 60% of patients maintained a response for 9 months based on IGF-1 levels.[19]

Response to therapy with octreotide is related to the presence and increased quantity of functioning somatostatin receptors located in the pituitary adenoma. Identification of patients who will most likely respond to octreotide prior to initiation of long-term therapy is important given the high cost of this medication and the inconvenience of subcutaneous or intramuscular drug administration. Suppression of serum GH concentrations after a single 50-mcg dose of octreotide has been used to predict a favorable long-term response to octreotide therapy, but the reliability of this test is not universally accepted.[7,26]

The initial dose of injectable octreotide for treatment of acromegaly is typically 100 mcg administered three times daily followed by either titration to a maximum of 1,500 mcg/day or transition to long-acting octreotide.[8] Some clinicians recommend a starting dose of 50 mcg every 8 hours, then increasing the dose to 100 mcg every 8 hours after 1 week, to improve the patient's tolerance of adverse GI effects. The dose can be increased by increments of 50 mcg every 1 to 2 weeks based on mean serum GH and IGF-1 concentrations. Patients who experience a significant rise in GH prior to the end of the 8-hour dosing interval may benefit from decreasing the dosing interval to every 4 to 6 hours. Although doses as high as 1,500 mcg/day have been used, doses greater than 600 mcg daily generally do not offer additional benefits, and most patients are adequately managed with 100 to 200 mcg three times daily.[8] Patients who have been maintained on subcutaneous octreotide for at least 2 weeks and have shown response to therapy can be converted to the long-acting depot form of octreotide. The initial dose of long-acting octreotide is 20 mg administered intramuscularly in the gluteal region every 28 days. Steady-state serum concentrations are not obtained until after 3 months of therapy. Therefore, dosage adjustments for long-acting octreotide should not be considered until after the 3rd dose. Some patients may require additional subcutaneous injections during the initial dose-titration phase in order to control symptoms. In patients who achieve more than 50% reduction in GH levels, the dose should be increased to 30 mg every 4 weeks. Some patients may require as much as 60 mg every 4 weeks.[27] In patients who have responded to and tolerated injectable octreotide or lanreotide, oral octreotide can be initiated on the day of a scheduled injection at a dose of 20 mg twice daily. The dose can be increased by 20 mg per day every 2 to 4 weeks based on IGF-1 levels and the patient's signs and symptoms to a maximum of 40 mg twice daily. As the oral formulation of octreotide exhibits pH-dependent absorption, clinicians should avoid drugs that increase gastric pH (eg, proton pump inhibitors) to maximize bioavailability.

Lanreotide (Somatuline Depot) is commercially available in the United States for monthly, deep subcutaneous administration. In addition to acromegaly, lanreotide is also indicated for the treatment of gastroenteropancreatic neuroendocrine tumors (GEP-NETs) and carcinoid syndrome. The efficacy of lanreotide for the treatment of acromegaly has been evaluated in several prospective multicenter clinical trials involving treatment-naïve and treatment-experienced patients who were switched from intramuscular octreotide LAR or intramuscular lanreotide LA to monthly deep subcutaneous lanreotide.[28] These studies have determined that deep subcutaneous lanreotide suppresses mean serum GH concentrations to less than 5 mcg/L (225 pmol/L) and normalizes serum IGF-1 concentrations to a similar extent as octreotide LAR and lanreotide LA. A 4-year follow-up of 23 patients treated with monthly deep subcutaneous lanreotide reported the drug to be well tolerated during long-term therapy with mean serum GH concentrations less than 5 mcg/L (225 pmol/L) in 62% of patients and normalization of serum IGF-1 concentrations in 43% of patients.[29] Analyses of trials investigating the effects of lanreotide on pituitary tumor mass have shown shrinkage in the majority of patients, and the response appears to be more prevalent in treatment-naïve patients and in patients with macroadenomas.[28,30] Well-designed trials directly comparing the efficacy of intramuscular octreotide LAR to deep subcutaneous lanreotide are currently lacking. However, these two agents are generally regarded to have comparable efficacy.[7,8]

Lanreotide (Somatuline Depot) is commercially available in the United States as 60-, 90-, and 120-mg prefilled syringes. In contrast to octreotide LAR and pasireotide, lanreotide does not need to be reconstituted prior to administration. The initial recommended dose of lanreotide is 90 mg given by deep subcutaneous injection in the superior external quadrant of the buttock every 28 days. Injection sites should be alternated between the left and right sides. The initial dose should be reduced to 60 mg every 28 days for patients with moderate or severe renal or hepatic impairment. After 3 months of therapy, the dose may then be titrated and/or frequency extended, based on serum GH concentrations, serum IGF-1 concentrations, and control of signs and symptoms of acromegaly.[28] Patients well controlled on lanreotide 60 or 90 mg every 28 days may consider an extended dosing interval of lanreotide 120 mg every 6 to 8 weeks. Increases in drug frequency greater than every 28 days or higher than 120 mg may be recommended for patients with partial responses to lanreotide.[31]

Pasireotide (Signifor LAR) for the treatment of acromegaly is commercially available in the United States in the form of a monthly intramuscular injection. Another formulation of pasireotide (Signifor) is approved for treatment of Cushing disease as a twice-daily subcutaneous injection. The efficacy of the long-acting pasireotide formulation has been evaluated in both drug-naïve patients and those inadequately controlled on long-acting octreotide or lanreotide.[32–35] In drug-naïve patients treated for 12 months, pasireotide suppressed mean serum GH concentrations to less than 2.5 mcg/L (113 pmol/L) and normalized serum IGF-1 concentrations in 38% compared to 23% with octreotide.[33] An extension study of up to 25 months noted long-term biochemical control (GH < 2.5 mcg/L [113 pmol/l] and normal IGF-1) in 48% with pasireotide compared with 45% with octreotide.[34] In patients inadequately controlled with octreotide or lanreotide, pasireotide resulted in biochemical control (GH <2.5 mcg/L [113 pmool/L]and normal IGF-1) in 15% to 20% of patients treated for 24 weeks.[35]

The initial recommended dose of pasireotide is 40 mg given by intramuscular injection every 28 days. The initial dose should be reduced to 20 mg every 28 days for patients with moderate or severe hepatic impairment. After 3 months of therapy, the dose may be titrated based on serum GH concentrations, serum IGF-1 concentrations, and control of signs and symptoms of acromegaly. Doses of pasireotide exceeding 60 mg every 28 days are not recommended.[32]

The most common adverse effects of somatostatin analog therapy are GI disturbances such as diarrhea, nausea, abdominal cramps, malabsorption of fat, and flatulence.[25,28,32] GI adverse effects occur in approximately 75% of patients but usually subside within 10 to 14 days of continued treatment. Octreotide can cause injection-site pain (4%-31%), conduction abnormalities and arrhythmias (9%), subclinical hypothyroidism (2%-12%), biliary tract disorders (4%-50%), and abnormalities in glucose metabolism (2%-18%). Lanreotide has been associated with injection-site reactions (9%), sinus bradycardia (3%), hypertension (5%), biliary tract disorders (20%), and abnormalities in glucose metabolism (7%). While adverse effects with pasireotide are similar to octreotide and lanreotide, the incidence of hyperglycemia is significantly greater (61%-67% vs 25%-30%), often requiring treatment with antidiabetes medications (38%-39% vs 6%).

Somatostatin analogs also inhibit cholecystokinin release and gallbladder motility, predisposing patients to the development of cholelithiasis.[36,37] The development of gallstones is a long-term adverse effect of somatostatin analog therapy and is dependent mainly on geographic factors, dietary habits, and length of treatment. The incidence of gallstones in patients with acromegaly receiving octreotide and lanreotide increases with the duration of therapy and has been reported to range from 20% to 50%.[25,28,32] However, most patients are asymptomatic, and the diagnosis of cholelithiasis usually is made following an ultrasonographic study that is not prompted by patient symptoms. It has been estimated that only 1% of patients will develop symptomatic gallstones during 1 year of octreotide treatment.[36] Because somatostatin analog-induced gallstones usually are present without symptoms, prophylactic cholecystectomy or medical therapy with ursodeoxycholic acid is not recommended. A small number of studies have suggested that the incidence of gallstone development may be lower with long-acting octreotide compared to subcutaneous octreotide.[25] However, further studies are needed to confirm this observation.

③The effect of somatostatin analogs on glucose metabolism in patients with acromegaly is multifactorial. Decreases in serum GH concentrations induced by somatostatin analogs should result in decreased hepatic gluconeogenesis and increased insulin-receptor sensitivity. However, somatostatin analogs also decrease insulin secretion and increase IGFBP-1, which is known to inhibit the insulin-like effects of IGF-1. In addition, somatostatin analogs delay the GI absorption of glucose, which may further alter glucose metabolism in patients with acromegaly.[38] Patients with diabetes should be actively monitored and glucose-lowering medications adjusted accordingly.[39] Risk factors associated with worsening glucose tolerance included female sex and elevated baseline insulin concentrations. Although somatostatin analogs have a beneficial effect on glucose tolerance in most patients, glucose determinations should be obtained frequently in the early stages of therapy.

Growth Hormone Receptor Antagonist

④Pegvisomant (Somavert) is a genetically engineered GH derivative that binds to, but does not activate, GH receptors and inhibits IGF-1 production. This agent is different from other medications used in the management of acromegaly because it does not inhibit GH production; rather, it blocks the physiologic effects of GH on target tissues. Therefore, GH concentrations remain elevated during therapy, and response to treatment is evidenced by a reduction in IGF-1 concentrations. Unlike somatostatin analogs, the pharmacologic activity of pegvisomant does not depend on the presence and quantity of somatostatin receptors in the pituitary tumor.[40] Studies evaluating the efficacy of pegvisomant have reported a dose-dependent normalization of IGF-1 concentrations in 54% to 89% of patients after 12 weeks of therapy and in 97% of patients after 1 year of therapy.[40,41] Significant improvements in the clinical signs and symptoms of acromegaly were reported and persisted throughout the 1-year treatment period.[41] An ongoing, international postmarketing surveillance registry (ACROSTUDY) reported normalization of IGF-1 serum concentrations in 73% of patients treated with pegvisomant for 10 years. Investigators note that failure to maintain IGF-1 normalization may reflect suboptimal dosing or more advanced disease than reported in the original studies.[42]

Adverse effects include injection-site pain, GI complaints such as nausea and diarrhea, and flu-like symptoms. Significant elevations in hepatic aminotransferase concentrations, which are generally reversible after discontinuation of the drug, have been reported.[43] Hepatic function tests should be monitored very closely during therapy as outlined in the product labeling and the drug should be used with caution in patients with baseline elevations in hepatic aminotransferase concentrations. GH concentrations may increase significantly during the first 6 months of pegvisomant therapy. Tumor growth has been reported in a small number of patients and there are theoretical concerns that the lack of GH feedback regulation on tumors that lead to persistently elevated GH concentrations may stimulate tumor growth or result in other long-term adverse effects. Results of the ongoing ACROSTUDY suggest that the rate of tumor growth is comparable to the background rate in acromegaly, and the incidence of hepatic aminotransferases greater than three times the upper limit of normal is low (3%).[42]

Pegvisomant is commercially available in the United States for daily subcutaneous use. It is recommended by the manufacturer that the initial 40-mg loading dose be administered under direct supervision by a physician but some authors note this is rarely done. Subsequent doses are self-administered by the patient starting at a dose of 10 mg daily. The dose can be adjusted in 5-mg increments based on serum IGF-1 concentrations every 4 to 6 weeks. The typical maintenance dose is 10 to 30 mg daily. Higher doses (40-60 mg daily) have been reported in patients who are younger, overweight, or have diabetes or high baseline IGF-1 levels.[43]

Based on high response rates in clinical trials, pegvisomant appears to be among the most effective agent for normalizing IGF-1 serum concentrations.

Current guidelines for acromegaly management suggest pegvisomant therapy for patients who have failed to achieve normalization of IGF-1 serum concentrations with other treatments or as the initial adjuvant medical therapy (weak recommendation, low-quality evidence).[7,8,11]

Combination Therapy

Several small studies have suggested that combination therapy with somatostatin analogs, dopamine agonists, or pegvisomant may be more effective than monotherapy.[7,8] Several of these trials have used doses lower than those typically used for monotherapy in order to reduce the risk of adverse effects. The Endocrine Society recommends the addition of pegvisomant or cabergoline in patients with inadequate response to a somatostatin analog (weak recommendation, low-quality evidence).[7] Because of the potential for additive adverse effects, combination therapy should be considered as a therapeutic option only for refractory patients who have not fully responded to monotherapy.[7,8,46]

Evaluation of Therapeutic Outcomes

Appropriate monitoring of medical therapy for acromegaly incorporates assessing for control of biochemical targets and clinical symptoms. An age-normalized serum IGF-1 and random GH are used to guide dosing and frequency of administration, and it is recommended to periodically assess these parameters as they correlate with disease control. Clinical symptoms that may relate to the tumor size (eg, headaches, visual disturbances) or elevations in GH or IGF-1 (eg, excessive sweating, arthralgia) should also be assessed periodically. Additional laboratory tests to monitor adverse events include serum glucose, for somatostatin analogs, and hepatic aminotransferases, for pegvisomant.

Conclusion

Acromegaly is a chronic debilitating disease characterized by excess GH secretion, most commonly caused by a GH-secreting pituitary adenoma. Transsphenoidal surgical resection of the adenoma is the current treatment of choice for most patients with acromegaly. Patients who are poor surgical candidates may receive radiation therapy or long-term pharmacologic therapy. Drug therapy options within the United States for acromegaly include dopamine agonists, somatostatin analogs, and pegvisomant.

GROWTH HORMONE DEFICIENCY

Short stature is a condition that is commonly defined by a physical height that is more than two standard deviations below the population mean for a given age, sex, and population.[47] It has been estimated that 2% of the population can be characterized as having short stature, although growth hormone deficiency as the primary cause is rare (estimated prevalence 1 in 4,000).[47] Short stature is a very broad term with many etiologies. A true lack of GH is among the least common causes and is known as GHD short stature. The etiology of GH deficiency may be congenital, resulting from various genetic abnormalities, such as GHRH deficiency, GH gene deletion, and developmental disorders including pituitary aplasia or hypoplasia; or acquired, resulting from hypothalamic or pituitary tumors, neurosurgery, cranial irradiation, head trauma, pituitary infarction, and CNS infections. However, the etiology is unclear in many cases, with no evidence of cranial pathology or known genetic abnormalities. In addition, psychosocial deprivation, hypothyroidism, poorly controlled diabetes mellitus, treatment of precocious puberty with LH-releasing hormone agonists, and pharmacologic agents such as glucocorticoids, methylphenidate, and dextroamphetamine may induce transient GH insufficiency.

Short stature also occurs with several conditions that are not associated with GH deficiency or insufficiency. These conditions include intrauterine growth restriction; constitutional growth delay; malnutrition; malabsorption of nutrients associated with inflammatory bowel disease, celiac disease, and cystic fibrosis; chronic renal failure; skeletal and cartilage dysplasia; and genetic syndromes such as Turner syndrome.[47,48] In addition, many children are diagnosed with idiopathic or normal variant short stature. These patients have heights that are significantly lower than the third percentile but have normal GH serum concentrations and no specific underlying explanation for short stature.[48]

Children with congenital GHD usually are born with an average birth weight. Decreases in growth velocity generally become evident between the ages of 6 months and 3 years.[47] In contrast, GH insufficiency may arise at any age during growth and development. The clinical characteristics of GHD or GH-insufficient children are listed in Table e98-3.[47]

TABLE e98-3

Clinical Presentation of Short Stature

General

- The patient will have a physical height that is greater than two standard deviations below the population mean for age and sex.

Signs

- The patient will present with reduced growth velocity and delayed skeletal maturation.
- Children with GH-deficient or GH-insufficient short stature may also present with central obesity, prominence of the forehead, and immaturity of the face.

Laboratory tests

- The patient will exhibit a peak GH concentration <10 mcg/L (450 pmol/L) following a GH provocation test. Reduced IGF-1 and concentrations may be present.
- Because GH deficiency may be accompanied by loss of other pituitary hormones, hypoglycemia and hypothyroidism may be noted.

GH, growth hormone.

Data from References [48,49].

Several factors must be considered in the diagnosis of GH deficiency or insufficiency. Standard epidemiologic growth charts developed by the National Center for Health Statistics typically are used to determine the percentile of anthropometric measurements, such as height, weight, and head circumference. Pubertal stage typically is determined using the Tanner method. Bone age is determined according to published standards, and growth velocity is calculated to determine the patient's height velocity percentile using standard growth-velocity charts.[47,48] GH deficiency is rarely seen in the absence of delayed skeletal maturation and decreased growth velocity. In addition, several provocative stimuli that induce GH secretion may be used diagnostically to determine GH status. Provocative pharmacologic GH stimuli include insulin-induced hypoglycemia, clonidine, L-dopa, arginine, glucagon, macimorelin and GHRH.[47] Traditionally, a subnormal GH response during childhood is arbitrarily defined as a peak GH serum concentration less than 10 mcg/L (450 pmol/L) during a 2-hour period after administration of one of these agents.[47] However, a lower cutoff may be used for the peak GH response, depending on the specific assay and GH reference product used. For prepubertal boys (>11) and girls (>10), priming with sex hormones to improve the specificity of GH provocation tests is suggested by the Pediatric Endocrine Society (conditional, low quality). Some patients exhibit clinical signs of GH deficiency, subnormal growth velocity, and delayed bone age despite GH levels that are within normal limits after provocative testing. This makes diagnosis in this group of patients very difficult. Diagnosis based on GH stimulation tests becomes further complicated because of the paucity of data reporting the normal range of GH concentrations after provocative testing in healthy children and the fact that commercial GH and IGF-1 assays currently available may not be equivalent. Although a gold standard for diagnosis of GHD does not exist, treatment is generally recommended for children who have "idiopathic short stature" and pass GH provocative testing but have most of the following criteria: height greater than 2.25 standard deviations below the mean for age, subnormal growth velocity; delayed bone age, low serum IGF-1 and/or IGFBP-3, and other clinical features consistent with GH deficiency.[47,49] Ultimately, careful consideration of multiple factors by a pediatric endocrinology specialist is required to correctly diagnose GH deficiency. Of note, more than half of children diagnosed with GH deficiency are found to secrete normal quantities of GH and IGF-1 in adulthood.[50]

Treatment

Pharmacologic Therapy

The treatment of GH deficiency with pituitary-derived human GH was first reported in the late 1950s.[51] Until the 1980s, GH was extracted from human pituitary tissue and the supply was very limited. Today, GH is produced using recombinant DNA technology and enables a much larger population to receive treatment.

Recombinant Growth Hormone

⑤Recombinant GH is currently considered the drug of choice for GHD short stature. GH replacement therapy in children with documented GHD short stature produces a significant improvement in growth velocity within the first year of therapy and significantly improves final adult height.[52,53] The initial increase in growth velocity often is referred to as *catch-up growth*. Studies evaluating the adult height of children who received recombinant GH therapy with currently recommended dosing regimens have reported average final adult heights ranging from 0.5 to 1.7 standard deviations below the population mean. Initiation of therapy at an early chronologic age, prior to the onset of puberty, is associated with a more favorable increase in final height.[47,52–55] Therefore, prompt diagnosis of GH deficiency and early initiation of replacement therapy with recombinant GH are crucial factors in optimizing the final adult height of children with GH deficiency.

The majority of short children in the United States do not have an identifiable medical cause for their condition, but with the widespread availability of several recombinant GH formulations, many children have received GH therapy regardless of the underlying etiology of their short stature. The use of recombinant GH therapy in children with non-GHD short stature, also referred to as idiopathic short stature (ISS), has been studied by many investigators and was approved by the FDA in 2003.[48] However, the use of GH therapy in this patient population remains controversial.[56,57] The Pediatric Endocrine Society recommends against routine use of GH in every child with ISS and suggests use only after assessment of physical and psychological burdens, along with a discussion of risks and benefits.[49] A meta-analysis of 38 clinical studies evaluating the efficacy of GH treatment in children with idiopathic short stature reported average increases in a final adult height of 4 to 5 cm (1.6-2 in.) following a mean duration of therapy of 4.7 years.[58] This corresponded to an increase above the predicted adult height of 0.56 to 0.63 standard deviations of the population mean. A more recent systematic review of GH treatment in idiopathic short stature noted that the final adult height gain is usually less than that seen in other FDA-approved conditions associated with growth failure, increasing adult height by about 4 cm (1.6 in.). The individual response to therapy is highly variable, and further studies are needed to identify responders.[59]

Recombinant GH has been shown to increase the short-term growth rate in pediatric patients with chronic renal insufficiency, Turner syndrome, idiopathic short stature, Prader–Willi syndrome, short stature homeobox gene (SHOX) deficiency, Noonan syndrome, and children born small for gestational age (SGA), and is approved by the FDA for treatment of growth failure associated with these conditions. GH is also FDA-approved for the treatment of adult GH deficiency, short bowel syndrome in patients receiving specialized nutritional support, and acquired immunodeficiency syndrome wasting syndrome. Adult patients with GH deficiency during childhood must have the diagnosis of GHD confirmed when they are adults. Long-term GH therapy in GHD adults significantly decreases body fat, increases muscle mass, and improves exercise capacity.[50] GH therapy in adults has not been definitively shown to improve the cardiac risk profile or bone mineral density, but it does appear to improve psychological well-being.[60] The Beers Criteria of the American Geriatrics Society recommends avoiding GH therapy except as replacement after pituitary gland removal because the risks in older adults outweigh any potential benefits[61] (strong recommendation, high-quality evidence).[59]

⑥Nine different recombinant GH products (somatropin) currently are available for use in the United States (Genotropin, Humatrope, Norditropin, Nutropin AQ, Omnitrope, Saizen, Serostim, Zomactin, and Zorbtive). A once-weekly analog of GH (somapacitan, Sogroya) has also been approved for adults and is currently undergoing phase 3 clinical trials in children. A once-weekly prodrug of somatropin (lonapegsomatropin, Skytrofa) has been approved for use in children and is currently under investigation for use in adults. Somatropin is composed of the same amino acid sequence as native human pituitary GH, while somapacitan has a single-substitution modification that enables it to bind to albumin. Both somapacitan and lonapegsomatropin can be used in treatment-naïve or treatment experienced individuals and may be a useful option in those who have trouble adhering to daily injections. Recombinant GH formulations must be administered by intramuscular or subcutaneous injection. Nutropin AQ, Norditropin, and Omnitrope do not require reconstitution, while the remaining products are formulated as lyophilized powders for injection, and patients must be instructed regarding proper administration. Needle-free injection devices are available for use, which may be useful for patients who experience significant fear of injections. The potency of GH products is expressed as international units per milligram (international units/mg), with 1 mg containing approximately 2.6 international units of GH. Direct comparisons between the different recombinant GH products have not been published. However, all GH products are generally considered to be equally effective, and some retrospective data suggest that switching formulations during the course of treatment does not negatively impact growth trajectory.[62] The recommended initial dose for GHD in children is 0.16 to 0.24 mg/kg/week[49] (strong recommendation, low-quality evidence). In contrast, initial dosing in adult GHD is often fixed, with lower doses recommended for patients over 60 years (100-200 mcg/day) compared to patients 30 to 60 years (200-300 mcg/day) and under 30 years (400-500 mcg/day).[50] Recombinant GH can be administered daily or in equal doses six times per week, depending on the specific GH product used.[47,51] Dosing regimens with greater frequency of administration have been shown to provide more favorable short-term growth responses.[49] While fixed-dose strategies have historically been used, most endocrinologists suggest that adjustments in GH replacement can be made based on IGF-1 serum concentrations based on the patient's age and sex.[63,64] GH replacement therapy should be initiated as early as possible after a diagnosis of GH insufficiency and continued until a desirable height is reached or growth velocity has decreased to less than 2.5 cm per year after the pubertal growth spurt. However, the suitable time point for discontinuation of therapy with growth-promoting doses remains controversial. The Pediatric Endocrine Society recommends treatment be given until the growth velocity slows to below 2 to 2.5 cm/year[49](strong recommendation, low-quality evidence). Glucocorticoids may inhibit the growth-promoting effects of recombinant GH, and concomitant administration of androgens, estrogens, thyroid hormones, or anabolic steroids may accelerate epiphyseal closure and compromise final height.

Large databases, such as the National Cooperative Growth Study (NCGS), the Kabi International Growth Study (KIGS), and the Australian and New Zealand growth database (OZGROW), have been developed to collect post-marketing adverse event data associated with recombinant GH. These databases are organized and maintained by pharmaceutical companies that manufacture GH products.[65–67] Results from the Safety and Appropriateness of Growth Hormone treatments in Europe (SAGhE) study provide additional long-term surveillance data from a noncommercial source.[67] Recombinant GH is generally well-tolerated in children, and adverse effects are relatively uncommon.[51,65–68] A small number of patients may complain of injection-site pain or arthralgias. Idiopathic intracranial hypertension, also known as *pseudotumor cerebri*, has been reported in a very small number of children receiving GH therapy. This condition usually develops within the first 8 to 12 weeks of treatment and presents with symptoms such as headache, blurred vision, diplopia, nausea, and vomiting.[51] The symptoms of idiopathic intracranial hypertension usually resolve after discontinuation of GH therapy, and long-term complications are rare. Cases of slipped capital femoral epiphysis have been reported in children with GHD who are receiving GH therapy.[51,67,68] This condition is thought to occur as a result of the increased width of the femoral plate during GH treatment, but it also has been reported in GHD children who are not receiving GH replacement. Patients with this condition typically complain of hip or knee pain. Slipped capital femoral epiphysis can be managed by an orthopedic surgeon, and GH therapy does not need to be discontinued. Because GH is known to cause decreased insulin sensitivity, hyperglycemia and diabetes mellitus may develop.[68] Patients who have specific predisposing risk factors for diabetes mellitus are at greatest risk for this adverse effect.[65,68] Glycosylated hemoglobin concentrations should be monitored in all patients receiving GH products.[47] GH could theoretically promote the growth of various types of neoplasms and increase tumor recurrence rates in patients with a history of malignancy.[47,65,68] Consensus statements for professional organizations recommend that GH can be safely used in those without a history of malignancy but note that current evidence is insufficient to conclude whether GH increases cancer risk or recurrence.[51,69] In 1988, a Japanese report indicated that children receiving GH therapy were twice as likely to develop leukemia as children who were not receiving the hormone. A more recent analysis of all collected reports of leukemia associated with GH therapy determined that these children had other leukemia risk factors (Fanconi anemia, Bloom syndrome, or history of cancer).[67] GH therapy in children without these risk factors does not appear to predispose children to develop leukemia.[51,67,69] Concerns have been raised from the SAGhE cohort about the possibility that childhood GH exposure may be associated with diseases that may not manifest until adulthood. Increased cardiac and cerebrovascular mortality rates were observed in adult French subjects treated with GH therapy as children, but similar results were not seen in subjects from Belgium, the Netherlands, and Sweden.[67,70] The observational design of these studies makes interpretation of the findings difficult. Additionally, it should be noted that some authors have stressed the importance of using growth velocity and provocative testing in deciding whom and when to treat, and at what doses.

Recombinant Insulin-Like Growth Factor-1

Recombinant IGF-1 (mecasermin [Increlex]) is approved by the FDA for the treatment of children with short stature due to severe primary IGF-1 deficiency (defined as children with height standard deviation score ≤–3.0 plus basal IGF-1 standard deviation score ≤–3.0, plus normal or elevated GH concentration) or GH gene deletion with neutralizing antibodies to GH. Recombinant IGF-1 products are not intended for use in subjects with secondary forms of IGF-1 deficiency, such as GH deficiency, malnutrition, hypothyroidism, or chronic treatment with pharmacologic doses of glucocorticoids. Recombinant IGF-1 products have been shown to increase growth velocity in children with short stature who have low IGF-1 serum concentrations and resistance to GH.[71–73] However, the efficacy of these agents is less than that reported with GH products in patients with GH deficiency.

The recommended dose of mecasermin is 0.04 to 0.12 mg/kg administered by subcutaneous injection twice daily. First-year growth and long-term outcomes are best with doses more than 0.1 mg/kg/dose, adjusted for increases in weight as the patient grows. Treatment continues until epiphyseal closure or attainment of full growth potential.[71,72] Because of the insulin-like effects of these products, patients should be monitored very closely for hypoglycemia, and the drug should be initiated at the lower end of the dosage range and administered with a meal or snack. Additional adverse effects experienced by patients receiving recombinant IGF-1 products include injection-site reactions, tonsillar/adenoidal hypertrophy, lymphoid hypertrophy, coarsening facial features, anaphylaxis, headache, dizziness, and arthralgia.[71–73] Intracranial hypertension has been reported in a small number of patients. Additional studies are needed to elucidate the role of recombinant IGF-1 products in the management of short stature not caused by GH gene deletion or GH receptor defects.

Evaluation of Therapeutic Outcomes

The large number of GHD disorders vary in their phenotype as well as biochemical and molecular characteristics. This likely explains the significant variability in the response observed in clinical trials with GH or IGF-1. Given this variability, and in the absence of specific and well-validated indicators of response, therapy must be individualized.[74] Appropriate monitoring of therapy for GHD and non-GHD short stature includes regular assessments of height, weight, growth velocity, serum IGF-1 concentrations, and bone age every 6 to 12 months. Additional laboratory tests to monitor for potential adverse effects include serum glucose concentration and thyroid function. The dose of GH should be periodically increased as weight increases in growing children.

Conclusion

GH deficiency during childhood results in short stature. Replacement with recombinant GH is the drug of choice for patients with GHD short stature, but its use for the treatment of non-GHD short stature remains controversial despite FDA approval for this indication. Recombinant GH has proven to be safe for use in children and is associated with few adverse effects. Preparations of IGF-1 may provide benefit for patients with non-GHD short stature. GH regimens can be particularly demanding and inconvenient for pediatric patients because they must be administered by subcutaneous injection.

HYPERPROLACTINEMIA

Prolactin is secreted in a pulsatile fashion by the lactotroph cells of the anterior pituitary, with the highest concentrations observed during sleep.[4] The secretion of prolactin is primarily regulated by the inhibitory effects of dopamine from the hypothalamus. Many factors can effect prolactin secretion (see Table e98-1). During pregnancy, prolactin serum concentrations substantially rise. All other conditions characterized by excess prolactin serum concentrations, known as *hyperprolactinemia*, are considered pathologic. Hyperprolactinemia is a state of persistent serum prolactin elevation. In the absence of stress, a prolactin serum concentration above the normal range (25 mcg/L ([1,090 pmol/L]) is generally considered indicative of hyperprolactinemia.[75] Hyperprolactinemia usually affects women of reproductive age.[75,76] The annual incidence of hyperprolactinemia in women between the ages of 25 and 34 years is approximately 24 cases per 1,000 person-years.[75]

Hyperprolactinemia has several etiologies. The most common causes are benign prolactin-secreting pituitary tumors, known as *prolactinomas*, and medications. Prolactinomas are classified based on size. Prolactin-secreting microadenomas are less than 10 mm in diameter and typically do not increase in size.[77] In contrast, macroadenomas are tumors with a diameter greater than 10 mm that continue to grow and can cause invasion of surrounding tissues.[4] In the presence of a prolactinoma, the elevation in prolactin serum concentration is generally proportional to the size of the tumor, with prolactin concentrations more than 500 mcg/L (22,000 pmol/L) typically diagnostic for a macroprolactinoma.[75–77]

⑦ Any pharmacologic agent that antagonizes dopamine or increases the release of prolactin can induce hyperprolactinemia (Table e98-4).[78] Antipsychotic medications are the most frequently reported agents to cause hyperprolactinemia due to their potent dopamine-receptor blockade. Serotonin is a strong stimulator of prolactin secretion and antidepressants such as selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase (MAO) inhibitors, tricyclic, and tetracyclic agents are associated with hyperprolactinemia.[78] The $5HT_1$ receptor agonist eletriptan has also been implicated as a potential cause of hyperprolactinemia.[79] Metoclopramide and domperidone, an antiemetic available in Europe, are potent dopamine-receptor antagonists reported to induce hyperprolactinemia.[78] Hormones such as estrogen and progesterone, commonly prescribed as oral contraceptives, can stimulate lactotroph growth to promote prolactin secretion and have been implicated in drug-induced hyperprolactinemia. Although the exact mechanism of action remains to be determined, the calcium channel-blocking agent verapamil has been associated with cases of hyperprolactinemia.[4,78] Methyldopa and reserpine, although not frequently used today, are antihypertensive agents that can stimulate prolactin secretion.[78] Prolactin concentrations may increase with the administration of GnRH agonists such as leuprolide or goserelin.[78] Other medications rarely reported to cause hyperprolactinemia include H_2-receptor blocking agents, benzodiazepines, opioids, and protease inhibitors.[4,78] Prolactin levels do not typically rise to more than 150 mcg/L (6,500 pmol/L) in most cases of drug-induced hyperprolactinemia. Measurement of serum prolactin concentrations prior to the initiation of therapy with medications known to cause hyperprolactinemia may obviate the need for extensive examination of pituitary function and aid the diagnosis of drug-induced causes.

TABLE e98-4

Drug-Induced Hyperprolactinemia

Dopamine antagonists

Antipsychotics
Phenothiazines
Metoclopramide
Domperidone

Prolactin stimulators

- Methyldopa
- Reserpine
- SSRIs
- $5HT_1$ receptor agonists
- Estrogens
- Progestins
- Protease inhibitors
- GnRH analogs
- Benzodiazepines
- Tricyclic and tetracyclic antidepressants
- MAO inhibitors
- H_2-receptor antagonists
- Opioids
- Cocaine

Other

- Verapamil

Data from References [76–78].

Less common etiologies of hyperprolactinemia include CNS lesions that physically compress the pituitary stalk and interrupt hypothalamic dopamine secretion.[75] Increased TRH concentrations in hypothyroidism can stimulate prolactin secretion and cause hyperprolactinemia. During conditions of renal or hepatic compromise, the clearance of prolactin is decreased, resulting in elevated prolactin concentrations.[75] Mutation of the prolactin receptor has also been identified as a cause of hyperprolactinemia.[76] Despite a rigorous diagnostic workup, the cause of hyperprolactinemia cannot always be determined. In such cases, the condition is referred to as *idiopathic hyperprolactinemia*.[75,76] It should be noted that many physiologic factors, such as stress (including the stress of phlebotomy), sleep, exercise, coitus, and eating, can induce transiently elevated prolactin levels.[4] Therefore, some clinicians may prefer obtaining multiple prolactin measurements to confirm the diagnosis.[75] Ideally, after an IV line is placed in the patient's arm, the patient should rest in a supine position or in a chair for 2 hours before prolactin samples are collected.

Elevated prolactin serum concentrations inhibit gonadotropin secretion and sex-steroid synthesis. Because prolactin concentrations greater than 60 mcg/L (2,600 pmol/L) are associated with anovulation, women with hyperprolactinemia typically present with menstrual irregularities such as oligomenorrhea or amenorrhea and infertility.[75] In addition, approximately 40% to 80% of women with hyperprolactinemia will have galactorrhea.[75,77]

The clinical presentation of patients with hyperprolactinemia is summarized in Table e98-5.[4,75–77]

TABLE e98-5

Clinical Presentation of Hyperprolactinemia

General

- Hyperprolactinemia most commonly affects women and is rare in men.

Signs and symptoms

- The patient may complain of symptoms related to local effects of the prolactin-secreting tumor, such as headache and visual disturbances that result from tumor compression of the optic chiasm.
- Female patients experience oligomenorrhea, amenorrhea, galactorrhea, infertility, decreased libido, hirsutism, and acne.
- Male patients experience decreased libido, erectile dysfunction, infertility, reduced muscle mass, galactorrhea, and gynecomastia.

Laboratory tests

- Prolactin serum concentrations at rest will be more than 25 mcg/L (1,090 pmol/L).

Additional clinical sequelae

- Prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreased bone mineral density and osteoporosis.
- The risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

Data from References [4,75,77].

The diagnosis of hyperprolactinemia, which requires a single prolactin serum concentration greater than 25 mcg/L (1,090 pmol/L), is relatively simple.[75] However, identifying the underlying cause is often challenging. Patients with modest prolactin elevations should have multiple prolactin serum determinations to eliminate transient increases in prolactin as the culprit. A careful medication history is essential, and the presence of hypothyroidism, renal failure, or hepatic dysfunction should be evaluated. If the cause of hyperprolactinemia remains ambiguous, a computed tomography scan or MRI study should be performed to determine the presence of a pituitary tumor.[75,77] If an underlying cause cannot be determined, the hyperprolactinemia is considered to be idiopathic. Prolactin serum concentrations may appear falsely elevated in the presence of macroprolactin, a large polymeric form of prolactin with negligible biological activity. Testing for the presence of macroprolactin is recommended for asymptomatic patients who have elevated prolactin serum concentrations.[75]

Treatment

The treatment of hyperprolactinemia should be directed toward the underlying cause. Treatment options for the management of prolactinomas include clinical observation, medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgical removal of the tumor.[4,75–77] Sex-steroid replacement should also be considered when clinically indicated.[75]

In cases of drug-induced hyperprolactinemia, discontinuation of the offending medication and initiation of an appropriate therapeutic alternative most often will normalize serum prolactin concentrations.[78] Aripiprazole, an atypical antipsychotic with partial dopamine D_2-receptor agonist activity, appears effective for managing antipsychotic-induced hyperprolactinemia as an adjunctive therapy and a therapeutic alternative when patients have been switched from an offending antipsychotic agent.[80] Metformin may also be useful for the management of antipsychotic-induced hyperprolactinemia.[81] In cases for which an appropriate therapeutic alternative does not exist, medical therapy with bromocriptine or cabergoline may be carefully considered (The Endocrine Society; weak recommendation with very low-quality evidence).[75]

Because prolactin-secreting microadenomas are very small and typically do not increase in size, treatment of these tumors is primarily directed toward alleviating symptoms.[75–77] The goal of therapy is to normalize prolactin serum concentrations and reestablish gonadotropin secretion to restore fertility and reduce the risk of osteoporosis. In patients with asymptomatic elevations in serum prolactin, observation and close follow-up are appropriate.[75] For women with amenorrhea who do not wish to become pregnant, dopamine agonist therapy may not be necessary. In these patients, sex hormone replacement and close follow-up may be sufficient.[75] Treatment goals are more aggressive in patients with prolactin-secreting macroadenomas because these tumors are larger and can cause invasion of local tissues and visual defects. Therefore, in addition to normalizing prolactin concentrations, tumor shrinkage and correction of visual defects are the primary goals of treatment.

Medical therapy with dopamine agonists usually is more effective than transsphenoidal surgery for both micro- and macro-prolactinomas.[4,75–77] Postsurgical cure rates depend on tumor type and the expertise of the neurosurgeon. Long-term cure rates are approximately 75% for microprolactinomas but only 34% for macroprolactinomas.[76] Transsphenoidal surgery for removal of prolactinomas is reserved for patients who are refractory to or cannot tolerate therapy with dopamine agonists and for patients with very large tumors that cause compression of adjacent tissues.[4,75–77] Radiation therapy may require several years for effective tumor shrinkage and reduction in serum prolactin concentrations. Thus, radiation therapy is reserved for patients with treatment-resistant macroprolactinomas.[77]

Pharmacologic Therapy

Medical therapy with dopamine agonists is very effective in normalizing prolactin serum concentrations, restoring gonadal function, and reducing tumor size. The Endocrine Society Clinical Practice Guidelines recommend treatment with dopamine agonists as first-line therapy (strong recommendation with high-quality evidence).[75] Cabergoline, a long-acting dopamine agonist that can be dosed less frequently, is considered the drug of choice for the medical management of prolactinomas because of its superior efficacy when compared to bromocriptine (strong recommendation with high-quality evidence).[75]

Bromocriptine

Bromocriptine, a D_2-receptor agonist, was commonly used in the treatment of hyperprolactinemia for more than 40 years.[82] It inhibits the release of prolactin by directly stimulating postsynaptic dopamine receptors in the hypothalamus. Hypothalamic release of dopamine (prolactin-inhibitory hormone) inhibits the release of prolactin. Decreases in serum prolactin concentrations occur within 2 hours of oral administration, with maximal suppression occurring after 8 hours. Prolactin suppression persists for up to 24 hours. Medical therapy with bromocriptine normalizes prolactin serum concentrations, restores gonadotropin production, and shrinks tumor size in approximately 80% of patients with microprolactinomas and 70% of patients with macroprolactinomas.[76]

For the management of hyperprolactinemia, bromocriptine therapy typically is initiated at a dose of 1.25 to 2.5 mg once daily at bedtime to minimize adverse effects.[4] The dose can be gradually increased by 1.25-mg increments every week to obtain desirable serum prolactin concentrations. Usual therapeutic doses of bromocriptine range from 2.5 to 15 mg/day, although some patients may require doses as high as 40 mg/day. Bromocriptine usually is administered in two or three divided doses, but once-daily dosing is also effective.[76]

The most common adverse effects associated with bromocriptine therapy include CNS symptoms such as headache, lightheadedness, dizziness, nervousness, and fatigue. GI effects such as nausea, abdominal pain, and diarrhea also are common. Bromocriptine should be administered with food and titrated slowly to decrease the incidence of adverse GI effects. Although most of these adverse effects diminish with continued treatment, approximately 12% of patients discontinue bromocriptine therapy due to adverse effects. Vaginal preparations of bromocriptine may be used in women to decrease the incidence of adverse effects associated with oral adminstration.[4,75]

Many patients with hyperprolactinemia are women with a principal complaint of infertility. Thus, the safety of bromocriptine in pregnancy must be considered. More than 6,000 pregnancies have been reported in women who received bromocriptine during pregnancy. The risk of spontaneous abortion or congenital anomalies does not appear to be increased.[75] Despite these data, discontinuation of therapy as soon as pregnancy is detected is recommended because the effects of in utero exposure to bromocriptine on gonadal function and fertility of the offspring remain unknown (The Endocrine Society; strong recommendation with low-quality evidence).[4,75,82] In patients with macroprolactinomas with rapid tumor expansion, bromocriptine therapy may need to be continued throughout pregnancy (The Endocrine Society; weak recommendation with low-quality evidence).

Cabergoline

⑧ Cabergoline is a long-acting dopamine agonist with high selectivity and affinity for dopamine D_2-receptors. Cabergoline effectively reduces serum prolactin concentrations and tumor size in patients with both microprolactinomas and macroprolactinomas.[75] Compared to bromocriptine, cabergoline is significantly more effective.[76,82] A systematic review and meta-analysis of four clinical trials comparing the efficacy of cabergoline and bromocriptine reported that cabergoline was significantly more effective in normalizing serum prolactin concentrations.[82] Cabergoline has also proved effective in patients who are intolerant of or resistant to bromocriptine and is as effective in men as in women with microprolactinomas and macroprolactinomas.[75]

Cabergoline is commercially available as 0.5-mg oral tablets. The initial dose of cabergoline for treatment of hyperprolactinemia is 0.25 to 0.5 mg once weekly or in divided doses twice weekly. This dose may be increased by 0.5-mg increments at 4-week intervals based on serum prolactin concentrations.[83] The usual effective dose is 0.5 to 1 mg weekly; doses more than 3.5 mg per week are rarely required.[76] However, doses as high as 12 mg weekly have been used safely in patients with treatment-resistant prolactinomas.[83] Following oral administration, peak serum concentrations are obtained within 2 hours, and food does not affect absorption. The elimination of cabergoline from the pituitary appears to be very slow; this may explain the long duration of action. Cabergoline is extensively metabolized in the liver by hydrolysis, and the dose should be reduced in patients with severe hepatic failure.

The most common adverse effects reported with use of cabergoline are nausea, vomiting, headache, nasal congestion, and dizziness.[77,82] These effects are similar to the adverse effects reported with bromocriptine. However, in a large comparative study evaluating bromocriptine and cabergoline, fewer patients receiving cabergoline reported adverse effects than did patients receiving bromocriptine. Only 3% of the patients in the cabergoline group withdrew from the study because of adverse effects versus 12% of patients taking bromocriptine.[84] Other adverse events associated with the use of cabergoline include mood disorders, exacerbation of existing psychosis, and poor impulse control.[76,77] As with other dopamine agonists, adverse events usually occur early in therapy and subside with continued use. A reduction in blood pressure has been observed in up to 50% of patients taking cabergoline; however, the incidence of symptomatic orthostatic hypotension has not been significant.[82,84] Transient increases in serum alkaline phosphatase, bilirubin, and aminotransferases have been reported in small numbers of patients receiving cabergoline.[84] Newly diagnosed cardiac valve regurgitation has been reported with cabergoline used in larger doses for the treatment of Parkinson disease.[76] Symptomatic cardiac valve abnormalities have not been observed with doses used for the treatment of prolactinomas.[76,77] However, data from one meta-analysis suggests a potential association between low-dose cabergoline and asymptomatic tricuspid regurgitation in patients treated for hyperprolactinemia.[85] Therefore, some clinicians recommend a baseline and routine follow-up echocardiography for patients receiving long-term cabergoline treatment for prolactinomas, especially if the dose exceeds 2 mg/week.[86]

⑨ Cabergoline use during pregnancy has not been extensively studied. Several case reports of women who received cabergoline therapy during the first and second trimesters of pregnancy have not documented an increased risk of spontaneous abortion, congenital abnormalities, or tubal pregnancy.[87] However, prospective data in large numbers of pregnancies are lacking. Because of the long half-life and limited data on cabergoline use in pregnancy, current guidelines recommend that women receiving cabergoline therapy who plan to become pregnant should discontinue the medication as soon as pregnancy is detected (The Endocrine Society; strong recommendation with low-quality evidence).[75]

Quinagolide, a D_2-receptor agonist used frequently in Europe, is dosed once daily. Quinagolide has been shown to be as effective as bromocriptine for the management of hyperprolactinemia and may be effective in the treatment of patients who are resistant to or intolerant of bromocriptine.[4]

Evaluation of Therapeutic Outcomes

Prolactin serum concentrations should be monitored every 3 to 4 weeks after the initiation of any dopamine-agonist therapy to assess the efficacy and appropriately titrate the dose.[75] Symptoms such as headache, visual disturbances, menstrual cycles in women, and sexual function in men should be evaluated to assess response to therapy. Once prolactin concentrations have normalized and symptoms have resolved with dopamine-agonist therapy, prolactin serum concentrations should be monitored every 6 to 12 months. In patients who have received medical therapy with a dopamine agonist for at least 2 years, therapy may be tapered or discontinued if normal serum prolactin concentrations are achieved in the absence of visible tumor (The Endocrine Society; weak recommendation with low-quality evidence).[75] Follow-up of such patients should include prolactin serum concentration measurements every 3 months for the first year (continued annually thereafter) with an assessment of MRI findings if prolactin concentrations are elevated.

Conclusion

Hyperprolactinemia is a common disorder that can have a significant impact on fertility. Hyperprolactinemia is most commonly caused by the presence of prolactin-secreting pituitary tumors and medications that antagonize dopamine or increase the secretion of prolactin. Available treatment options for this disorder include medical therapy with dopamine agonists, radiation therapy, and transsphenoidal surgery. In most cases, medical therapy with dopamine agonists is considered the most effective treatment. Cabergoline is the drug of choice because it is better tolerated and more effective than bromocriptine.

PANHYPOPITUITARISM

⑩ Panhypopituitarism is a condition of complete or partial loss of both anterior and posterior pituitary function resulting in multiple pituitary hormone deficiencies. Patients with panhypopituitarism may have ACTH deficiency, gonadotropin deficiency, GH deficiency, hypothyroidism, and hyperprolactinemia. Panhypopituitarism is classified as either primary or secondary based on the etiology. Primary panhypopituitarism involves an abnormality within the secretory cells of the pituitary. Secondary panhypopituitarism is caused by a lack of proper external stimulation needed for the normal release of pituitary hormones. Some of the most common causes of panhypopituitarism include pituitary tumors, ischemic necrosis of the pituitary, surgical trauma, irradiation, and CNS infections. Pharmacologic treatment of panhypopituitarism is essential and consists of the replacement of pituitary hormones to address specific deficiencies. Replacement most often consists of glucocorticoids, thyroid hormone preparations, and sex steroids. Administration of recombinant GH also may be necessary. Patients with panhypopituitarism will need lifelong replacement therapy and close monitoring of multiple homeostatic functions.

ABBREVIATIONS

AACE	American Association of Clinical Endocrinologists
ACTH	adrenocorticotropic hormone
CNS	central nervous system
CRH	corticotropin-releasing hormone
FSH	follicle-stimulating hormone
GEP-NETs	gastroenteropancreatic neuroendocrine tumors
GH	growth hormone
GHD	growth hormone deficiency/growth hormone–deficient)
GHRH	growth hormone-releasing hormone
GI	gastrointestinal
GnRH	gonadotropin-releasing hormone
IGF	insulin-like growth factor
IGFBP-3	insulin-like growth factor-1 binding protein-3
LH	luteinizing hormone
MAO	monoamine oxidase
MRI	magnetic resonance imaging
OGTT	oral glucose tolerance test

SELF-ASSESSMENT QUESTIONS

1. Which of the following physiologic functions is *not* regulated by anterior pituitary hormones?

A. Growth

B. Thyroid function

C. Ovulation

D. Uterine contraction

2. Which of the following clinical characteristics is common to acromegalic patients?

A. Diarrhea

B. Increased shoe size

C. Weight loss

D. Alopecia

3. The preferred initial treatment option for a patient recently diagnosed with acromegaly is:

A. Bromocriptine.

B. Lanreotide.

C. Transsphenoidal surgery.

D. Radiation therapy.

4. KL is a 58-year-old man who was recently diagnosed with acromegaly. His past medical history is significant for type 2 diabetes and obesity. He is currently complaining of fatigue, joint pain, increased sweating, and headaches. He is not a candidate for transphenoidal surgery. Which of the following treatments is most appropriate for first-line treatment of KL's symptoms?

A. Bromocriptine

B. Cabergoline

C. Octreotide

D. Radiation therapy

5. Which of the following information is most important to provide to a patient with a new prescription for lanreotide?

A. Concomitant therapy with ursodeoxycholic acid is needed to prevent gallstones.

B. The most common adverse effect of lanreotide therapy is headache.

C. A standard multiple vitamin is recommended during therapy.

D. GI adverse effects should subside within 10 to 14 days of therapy.

6. Which of the following clinical characteristics is common to patients with GH-deficient short stature?

A. Normal GH serum concentrations

B. Physical height <2 standard deviations below the population mean

C. Malnutrition

D. Hyperglycemia

7. Which of the following assessments need to be considered for the diagnosis of GH deficiency?

A. Bone age and growth velocity

B. Random GH level

C. Serum glucose concentrations

D. Body weight

8. For which of the following conditions does recombinant human growth hormone therapy have a definitive role?

A. Chronic fatigue syndrome

B. GH-deficient short stature

C. Natural aging

D. Depression

9. Which of the following parameters should be monitored in a patient receiving recombinant human growth hormone therapy?

A. Prolactin

B. Menstrual cycles in women

C. Echocardiography

D. Insulin growth factor 1

10. Which of the following clinical characteristics is common in women with hyperprolactinemia?

A. Menstrual irregularities

B. Darkened skin

C. Dry mouth

D. Increased blood glucose

11. Which of the following classes of medications is most likely to cause drug-induced hyperprolactinemia?

A. β-blockers

B. Antidepressants

C. Antihistamines

D. Oral contraceptives

12. LJ is a 29-year-old woman who has been diagnosed with a prolactin-secreting adenoma that is 8 mm in diameter. She complains of amenorrhea for 1 year and galactorrhea from both breasts. Which of the following treatments is most appropriate for first-line treatment of LJ's symptoms?

A. Radiation therapy

B. Transsphenoidal surgery

C. Dopamine agonist therapy

D. Somatostatin analog therapy

13. Which of the following dopamine agonists would be an appropriate choice for a patient with hyperprolactinemia who is trying to conceive?

A. Cabergoline

B. Ropinirole

C. Bromocriptine

D. Pramipexole

14. CM is a 30-year-old woman diagnosed with hyperprolactinemia. She recently began therapy with cabergoline. Which of the following adjunctive medications should be considered for CM?

A. Human growth hormone

B. Oral contraceptives

C. Multivitamins

D. Antacids

15. Which of the following treatments may be required for patients with panhypopituitarism?

A. Pasireotide

B. Cabergoline

C. Pegvisomant

D. Levothyroxine

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** See Table e98-1. The posterior pituitary gland is involved with uterine contraction via the secretion of oxytocin. The anterior pituitary gland is involved with growth via secretion of GH, thyroid function via secretion of TSH, and ovulation via secretion of LH/FSH. See the Anatomy and Physiology section for more information on pituitary gland regulation.

2. **B.** See Table e98-2 and clinical presentations of Acromegaly for more information. Increased shoe size is a sign that patients may exhibit.

3. **C.** Transsphenoidal surgery is considered for most patients unless the pituitary tumor is unresectable or the patient is a poor surgical candidate. See Treatment section of Growth Hormone Excess and Fig. e98-2 for more information on the approach to the treatment of acromegaly.

4. **C.** In patients who are poor candidates for surgery, somatostatin analogs, such as octreotide, are recommended primary therapy. See Somatostatin Analogs under Treatment section of Growth Hormone Excess and Fig. e98-2 for more information on the approach to the treatment of acromegaly

5. **D.** Prophylactic therapy for gallstones is not recommended as somatostatin-induced gallstones rarely present with symptoms. One of the first symptoms of acromegaly that may subside with somatostatin therapy is a headache. GI adverse effects of somatostatin analogs are seen in 75% of patients but usually subside within 10 to 14 days. See Somatostatin Analogs under Treatment section of Growth Hormone Excess for discussion on

adverse effects

6. **B.** Patients will have a physical height greater than 2 standard deviations below the population mean for a given age and height. See Table e98-3 for the clinical presentation of short stature.

7. **A.** See Table e98-3 for laboratory tests commonly used for evaluation of GH deficiency. See GH deficiency section for discussion on presentation.

8. **B.** Growth hormone is indicated for GH-deficient short stature. See Recombinant Growth Hormone section discussion on indications and uses.

9. **D.** See Evaluation of Therapeutic Outcomes section under Growth Hormone Deficiency. Appropriate monitoring of therapy for efficacy includes regular assessments of height, weight, growth velocity, IGF-1, and bone age every 6 to 12 months in addition to glucose and thyroid function for monitoring adverse effects.

10. **A.** Menstrual irregularities. Women with hyperprolactinemia typically present with menstrual irregularities such as oligomenorrhea or amenorrhea because elevated prolactin concentrations inhibit gonadotropin secretion and sex-steroid synthesis. See Table e98-5 for more information about the clinical presentation of patients with hyperprolactinemia.

11. **B.** Antidepressants. SSRIs, MAO inhibitors, and tricyclic and tetracyclic agents are associated with hyperprolactinemia because serotonin is a strong stimulator of prolactin secretion. See Table e98-4 in the chapter for more information.

12. **C.** Dopamine agonist therapy. Medical therapy with dopamine agonists is usually more effective than transsphenoidal surgery and/or radiation for prolactin-secreting adenomas.

13. **C.** Bromocriptine. Information regarding the safety of dopamine agonists during pregnancy is more robust with bromocriptine. However, bromocriptine should be discontinued as soon as pregnancy is detected because the effects of in utero exposure to bromocriptine on gonadal function and fertility of the offspring remain unknown.

14. **B.** Oral contraceptives. Elevated prolactin concentrations inhibit gonadotropin secretion and sex-steroid synthesis. Therefore, sex-steroid replacement should be considered to reduce the risk of osteoporosis.

15. **D.** Panhypopituitarism results in complete or partial loss of anterior and posterior pituitary function. Therefore, pharmacologic treatment consists of replacement of specific pituitary hormones based on individual deficiencies.

Chapter e106: Function and Evaluation of the Immune System

Daniel A. Zlott; Geoffrey M. Thiele

KEY CONCEPTS

KEY CONCEPTS

① Cells of the immune system are derived from the pluripotent stem cell. Hematopoiesis is closely regulated to maintain adequate numbers of different cell types. The development of these different -cells or cell lineages depends on cell-to-cell interactions and hematopoietic growth factors.

② Upon activation, dendritic cells (DCs) express higher concentrations of major histocompatibility complex class II molecules, B7-1, B7-2, CD40, ICAM-1, and LFA-3 molecules than other antigen-presenting cells (APCs). They also produce more IL-12. These differences may explain why DCs are the most efficient APC.

③ A T-lymphocyte expresses hundreds of T-cell receptors (TCRs). All the TCRs expressed on the surface of an individual T-lymphocyte have the same antigen specificity.

④ An immature B-lymphocyte expresses thousands of membrane-bound surface immunoglobulin (sIg) as IgM (monomeric) or IgD, all with the same specificity (ie, antigen-binding site). Upon antigen stimulation and T-cell help, the immature B-lymphocyte matures (proliferates, class-switches and becomes a plasma cell) to secrete different isotypes (eg, IgM [pentamer], IgA, immunoglobulin G [IgG], and IgE) with the same specificity as the original membrane-bound sIg.

⑤ Serum protein electrophoresis determines the total concentration of all circulating proteins, including the immunoglobulins (ie, IgG, IgA, IgM, IgD, and IgE). The concentration of the individual isotypes can be determined with isotype-specific quantification methods. Most clinical laboratories measure only IgG, IgM, and IgA because they are the most prevalent isotypes in the bloodstream. In patients with allergic disorders, measurement of IgE is rarely useful.

⑥ An understanding of the mechanism of action of immunomodulators allows a clinician to anticipate potential adverse drug reactions. The benefit of manipulating immune responses must be balanced with the potential consequences and long-term sequela (eg, tumor growth, infections, autoimmune reactions) of such manipulation.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the following video to learn more about the different ways clinicians use the immune system to treat cancer. IMMUNOTHERAPY: The Path to a Cancer Cure (For Clinicians), https://www.youtube.com/watch?v=UbFjiWOBErA. As you read the chapter, note which strategies for modulating the immune response for therapeutic purposes were discussed in the video.

INTRODUCTION

The immune system is a complex network of barriers, organs, cellular elements, and molecules that interact to defend the body against invading pathogens. The *immune system* is actually composed of two distinct systems of immunity: innate immunity and adaptive immunity. Innate immunity includes a series of nonspecific barriers (physical and chemical), along with cellular and molecular elements strategically deployed and positioned to prevent or quickly neutralize infection. Adaptive immunity works in concert with the innate immune system. In contrast to innate immunity, adaptive immunity constantly evolves and adapts to invading pathogens. The hallmarks of the adaptive immune response are *diversity*, *memory*, *mobility*, *self-versus-nonself discrimination*, *redundancy*, *replication*, and *specificity*.[1] *Diversity* is the capability of the immune system to respond to many different pathogens or strains of pathogens. Immunological *memory* ensures a quicker and more vigorous response to a subsequent encounter with the same pathogen. If an individual has encountered something before, the odds are good that they will encounter it again, so the individual will make more of these cells and have them ready. *The mobility* of components of the immune system enables local reactions to provide systemic protection. *Discrimination of self-versus-nonself* helps prevent the immune system from responding to our own healthy tissues, and thus results in self-tolerance. *Redundancy* is the ability of the immune system to produce components with similar biological effects from multiple cell lines, such as inflammatory cytokines. *Replication* of the cellular components of the immune system amplifies the immune response. *Specificity* is the ability of the immune system to distinguish between dissimilar antigens.

MAJOR TISSUES AND ORGANS OF THE IMMUNE SYSTEM

While numerous cells of the immune system have the ability to migrate to most body tissues, some tissues and organs serve as key members of the immune system. These include primary and secondary lymphoid tissues and organs. *Primary lymphoid tissues and organs*, the bone marrow and thymus, provide an environment for the development and maturation of select cells of the immune system. It is here that these select cells of the immune system mature and become tolerant of self and competent to respond to foreign antigens. Importantly, no immune response occurs in these sites. *Secondary lymphoid organs* provide an environment where various cells of the immune system interact with and respond to antigens.[2]

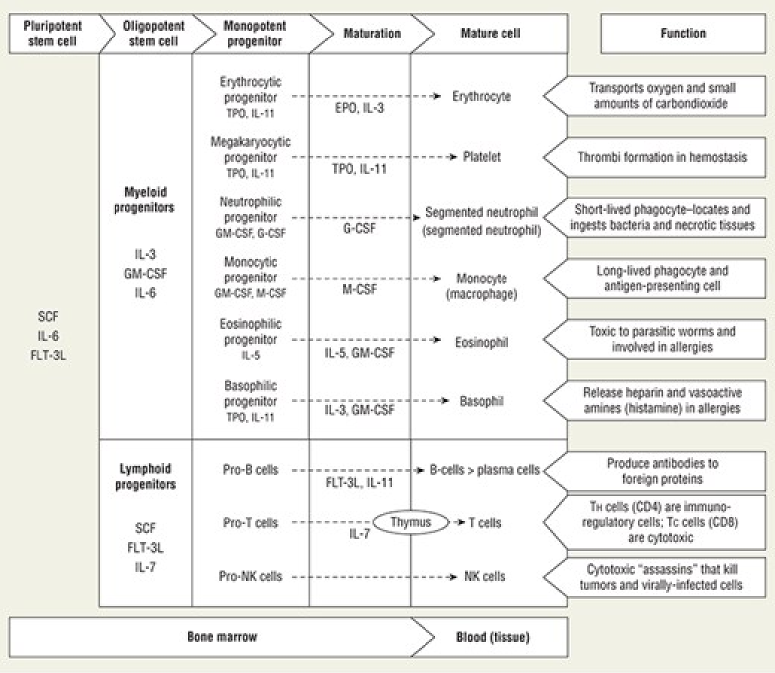
Primary Lymphoid Tissues

Bone Marrow

① The bone marrow is the predominant primary lymphoid tissue of the body because it is the source of all cellular elements of the blood (erythrocytes, leukocytes, and thrombocytes [ie, platelets]). The few exceptions to this rule are mostly confined to fetal development when some blood cells are transiently produced in the yolk sac, liver, spleen, thymus, and lymph nodes.[3] Regardless of where they are formed, all blood cells arise from common self-renewing pluripotent stem cells via the process of *hematopoiesis* (Fig. e106-1). During hematopoiesis, pluripotent stem cells differentiate along particular myeloid and lymphoid lineages to produce the leukocytes of the immune system, erythrocytes, and thrombocytes.[4,5] Hematopoiesis is controlled by soluble mediators called hematopoietic growth factors (ie, cytokines) or colony-stimulating factors (CSFs) that are multifunctional and stimulate growth, survival, proliferation, differentiation, maturation, and functional activation.[6] The destiny of the leukocytes (if they survive the maturation process) is to become mature cells of the immune system directly from the bone marrow (all leukocytes except T-lymphocytes) or to migrate out of the bone marrow to continue their maturation elsewhere (T-lymphocytes in the thymus). Selected hematopoietic growth factors are identified in Fig. e106-1, and a more comprehensive list is given in Table e106-1. Four human hematopoietic cytokines have one or more recombinant products that are FDA approved for clinical use: erythropoietin (EPO); granulocyte colony-stimulating factor (G-CSF); granulocyte-macrophage colony-stimulating factor (GM-CSF); and interleukin 11 (IL-11).[7] In addition, two small molecule thrombopoietin receptor agonists, eltrombopag and romiplostim, are FDA approved for the treatment of various autoimmune-mediated platelet disorders.[8,9]

FIGURE e106-1

Basic model of hematopoiesis, outlining the various pathways blood cells taken from their origin as bone marrow stem cells through stages in which they are progressively selected to become monopotent mature cells with specific functions. Selected hematopoietic growth factors include EPO, erythropoietin; FLT-3L, fms-like tyrosine kinase ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; NK, natural killer; SCF, stem cell factor; TPO, thrombopoietin.



Pluripotent stem cell
Oligopotent stem cell
Monopotent progenitor
Maturation
Mature cell
Function
SCF
IL-6
FLT-3L
Myeloid progenitors
IL-3
GM-CSF
IL-6
Erythrocytic progenitor
TPO, IL-11
EPO, IL-3
Erythrocyte
Transports oxygen and small amounts of carbondioxide
Megakaryocytic progenitor
TPO, IL-11
TPO, IL-11
Platelet
Thrombi formation in hemostasis
Neutrophilic progenitor
GM-CSF, G-CSF
G-CSF
Segmented neutrophil (segmented neutrophil)
Short-lived phagocyte–locates and ingests bacteria and necrotic tissues
Monocytic progenitor
GM-CSF, M-CSF
M-CSF
Monocyte (macrophage)
Long-lived phagocyte and antigen-presenting cell
Eosinophilic progenitor
IL-5
IL-5, GM-CSF
Eosinophil
Toxic to parasitic worms and involved in allergies
Basophilic progenitor
TPO, IL-11
IL-3, GM-CSF
Basophil
Release heparin and vasoactive amines (histamine) in allergies
Lymphoid progenitors
SCF
FLT-3L
IL-7
Pro-B cells
FLT-3L, IL-11
B-cells > plasma cells
Produce antibodies to foreign proteins
Pro-T cells
IL-7
Thymus
T cells
TH cells (CD4) are immuno-regulatory cells; TC cells (CD8) are cytotoxic
Pro-NK cells
NK cells
Cytotoxic "assassins" that kill tumors and virally-infected cells
Bone marrow
Blood (tissue)

TABLE e106-1

Hematopoietic Growth Factors or Colony-Stimulating Factors

Cytokine	Sources	Principal Effects
EPO	Kidney, liver	Erythrocyte production and maturation
GM-CSF	T-lymphocytes, macrophages, bone marrow stromal cells	Maturation and activation of granulocytes, monocytes/macrophages, and eosinophils
G-CSF	Macrophages, bone marrow stromal cells	Maturation and activation of neutrophils
M-CSF	Macrophages, bone marrow stromal cells	Maturation and activation of monocytes/macrophages
TPO	Liver, kidney	Platelet production
SCF	Bone marrow stromal cells, constitutively	Stem cell and progenitor cells activation
FLT-3L	Bone marrow stromal cells	Early acting growth factor
IL-3	T-lymphocytes, macrophages	Maturation and differentiation of hematopoietic and mast cells
IL-5	Activated T-lymphocytes	Eosinophil production
IL-1	Activated T-lymphocytes, bone marrow stromal cells	Progenitor cell stimulation
IL-7	Bone marrow stromal cells	T-cell maturation/survival
IL-11	Bone marrow stromal cells	Growth factor for B-lymphocytes and megakaryocytes

EPO, erythropoietin; FLT-3L, fms-like tyrosine kinase ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony- stimulating factor; SCF, stem cell factor; TPO, thrombopoietin.

Thymus

The thymus is a bilobed primary lymphoid organ located in the superior mediastinum between the aorta and the sternum. Its primary function is to produce mature T-cells (thymus-dependent lymphocytes), the leukocytes responsible for cell-mediated immunity, including cytotoxic actions and immunoregulation. Through an intricate multistep process called thymic education, T-cells that do not react to self and have the appropriate receptors are considered beneficial to the immune system and leave the thymus. T-cells that fail the thymic education test (estimated at >99% of all T-cells) are eliminated via apoptosis.[1]

Secondary Lymphoid Tissues

Spleen

The spleen is a slender elongated secondary lymphoid organ located in the upper left quadrant of the abdomen that receives blood from the splenic artery. Although it is not a vital organ, it functions as an immunological filter of the blood and destroys defective and old erythrocytes. It contains compartments designated as red pulp and white pulp. The white pulp provides an environment for the interaction of B-cells and T-cells where debris in the blood can interact with antigen-presenting cells (APCs), T-cells, and B-cells to initiate cell-mediated immune responses (T-cells) and antibody production (B-cells). The red pulp serves as a site of red blood cell degradation. The spleen sequesters many cellular elements (leukocytes, erythrocytes, and platelets) and can become dangerously congested during a strong inflammatory response and result in *splenomegaly*.

Lymph Nodes

Lymph nodes are normally small BB-sized lymphoid organs widely distributed between the groin and the neck. While the spleen filters blood, lymph nodes act as immunological filters for interstitial lymphatic fluid from the body's tissues. Lymph nodes provide an environment for the interaction of debris with APCs and other immune cells (T-cells and B-cells).[2] Lymph nodes may sequester activated immune cells (or tumor cells) and become inflamed and engorged (ie, lymphadenopathy).

Mucosa-Associated Lymphoid Tissue

Mucosa-associated lymphoid tissue (MALT) is the most extensive component of human lymphoid tissue and is distributed along mucosal linings of the body.[10] MALT may consist of well-defined networks of primary lymphoid follicles and other associated immunocompetent cells (adenoids, appendix, intestinal Peyer's patches, and tonsils), small solitary lymph nodes, or loosely organized clusters of lymphoid cells that are found in intestinal villi. The primary function of these tissues is to filter, trap, and remove pathogens that breach mucosal surfaces. In addition to neutralizing pathogens, MALT generates plasma cells (activated B-cells) that secrete antibodies, some of which are of the secretory IgA class of immunoglobulins with unique components to enable increased longevity in mucosal sites.

As mentioned earlier, the immune system includes two functional divisions: (a) The *innate* or nonspecific immune response, which encodes evolutionary genes aimed at providing rapid responses against nonmammalian targets; and (b) the *adaptive* or specific immune response, which uses cells that can rearrange their DNA to create specific structures on the T-cell receptor (on T-cells) and surface immunoglobulin (sIg) (on B-cells) which bind individual antigens or proteins (Table e106-2).[11] While we tend to classify these as two separate models for simplicity, these divisions extensively interact with the adaptive immune response driving the innate immune response.[12] An understanding of each component of the immune system and the consequences of disrupting homeostasis is essential to appropriately dose, administer, and monitor the effect of medications given to manipulate immune responses.

TABLE e106-2

Functional Divisions of the Immune System

	Innate	Adaptive
Exterior defenses	Skin, mucus, cilia, normal flora, saliva, low pH of the stomach, skin, genitourinary tract	None
Specificity	Limited and fixed	Extensive
Memory	None	Yes
Time to response	Hours	Days
Soluble factors	Lysozymes, complement, C-reactive protein, interferons, mannose-binding lectin, antimicrobial peptides[a]	Antibodies, cytokines
Cells	Neutrophils, monocytes, macrophages, natural killer cells, eosinophils	B-lymphocytes, T-lymphocytes

[a] Cathelicidins α-defensins, β-defensins.

METHODS TO DISTINGUISH SELF FROM NONSELF

The immune system is designed to attack and destroy a broad spectrum of foreign antigens/pathogens. However, the immune system must distinguish self from nonself, through a process now known as *self-tolerance*. If this did not occur, the immune system could direct an immune response against self-tissues.[13] The body employs many measures to avoid attacking itself, but when self-tolerance fails, the development of an autoimmune disease is often the result.

Innate Immune System

Physical Defense

Physical and chemical defenses are the most rudimentary form of innate immunity and the first line of defense against invading pathogens. The skin, the largest organ of the body, has the primary role of providing a physical defense. Alterations in the skin, such as burns or abrasions, allow a potential portal of entry for pathogens. The rapid turnover of intestinal cells also limits systemic infection as cells, including infected cells, are sloughed frequently. Drugs, such as cell-cycle, phase-specific antineoplastic agents, can disrupt the sloughing process and leave the patient at an increased risk for infections. Likewise, the respiratory tract has its forms of physical defense. The mucus coating the epithelial cells prevents microorganisms from adhering to cell surfaces, and the cilia lining the epithelium of the lungs repels inhaled organisms. The combination of cilia, mucus, and reactive coughing provides a natural barrier to invasion via the respiratory tract. The low pH of the stomach (pH 1-2) is inhospitable to most organisms and is a chemical defense resulting in the death of microorganisms. Other examples of mechanical or chemical defenses include normal urine flow through the urethra, lysozymes in tears and saliva, and the normal flora in the throat, the lower GI tract, and the genitourinary tract. Disruption of the normal physical and chemical defense systems through mechanical ventilation, for example, places the host at substantial risk for penetration by a pathogenic organism.[14]

Phagocytosis and Opsonization

If an infectious pathogen invades and infiltrates through a host's physical and chemical defense systems, the cells of the innate immune system are activated to halt the progression of the infection. These cells are present from birth and use a preexisting, but limited, repertoire of unique receptors to recognize and destroy pathogens. Innate immune cells include subgroups of leukocytes: monocytes/macrophages, neutrophils, basophils, mast cells, and eosinophils. When stimulated by a foreign pathogen, mast cells and basophils secrete inflammatory mediators. Monocytes/macrophages, neutrophils, mast cells, and eosinophils act as phagocytes. Phagocytes are cells that recognize, internalize, and degrade the invading pathogens. This process may occur in two ways: opsonin-dependent or opsonin-independent phagocytosis. For opsonin-dependent phagocytosis, opsonins like antibody (eg, IgG), complement (eg, C3b), or lectin (eg, C-reactive protein) coat the infectious pathogen by sticking to conserved structures on the infectious pathogens. Once the pathogen is opsonized, the opsonin (antibody, complement, or lectin) binds to the specific receptors on the phagocyte (Fig. e106-2) and activates the phagocytic process. For opsonin-independent phagocytosis, innate leukocytes use pattern recognition receptors (PRRs), which bind to highly conserved structures present on a large number of different microorganisms. PRRs on the phagocytes directly recognize the conserved ligands, also known as Pathogen Associated Molecular Patterns (PAMPs), on the surfaces of infectious pathogens (Table e106-3), leading to the immediate phagocytosis of the pathogen (see Fig. e106-2). PRRs include the macrophage mannose receptor, macrophage scavenger receptor, and members of the toll-like receptor family. Toll-like receptors are a family of PRRs on the cell- surface of innate leukocytes. To date, at least 10 toll-like receptors have been identified in humans. They recognize a broad spectrum of conserved structures ranging from lipopolysaccharide and flagellin on bacteria, to zymosan on yeast, to double-stranded RNA from RNA viruses (see Table e106-3). Binding of the PAMPs to the toll-like receptors (a PRR) allows the phagocyte to recognize and engulf the pathogen. Binding of toll-like receptors (PRRs) to their corresponding PAMPs also results in the secretion of chemokines, inflammatory cytokines, and antimicrobial peptides; increased expression of costimulatory proteins (eg, B7) and major histocompatibility complex (MHC) molecules by the phagocyte; and the recruitment and activation of antigen-specific lymphocytes.[12,15,16]

FIGURE e106-2

Phagocytosis of bacteria by macrophages, dendritic cells (DCs), and neutrophils. Macrophages, DCs, and neutrophils recognize bacteria opsonized (coated) with antibody or complement (C3b). On the surface of macrophages, DCs, and neutrophils reside receptors for antibody (Fc receptors) and complement (CR1, CR3, and CR4). In addition, these cells may recognize the bacteria by pattern recognition receptors on the surface of macrophages, DCs, and neutrophils. Pattern recognition receptors include toll-like receptors, scavenger receptors, and mannose receptors.

TABLE e106-3

Ligands for Pattern Recognition Receptors

Pathogen Ligand	Type of Organism
Lipoteichoic acid	Gram-positive organisms
Lipopolysaccharide	Gram-negative organisms
Mannose	Fungi, gram-positive, gram-negative
Double-stranded RNA	RNA viruses
Triacyl lipopeptides	Gram-positive, gram-negative
Peptidoglycans	Gram-positive
Bacterial flagella	Various

Cells of the Innate Immune System

Neutrophils, eosinophils, and basophils are considered granulocytes because they have numerous cytoplasmic granules that contain inflammatory mediators or digestive enzymes. Their names are derived from their staining characteristics. For example, neutrophils are named because they stain a neutral pink while basophils are named because they are easily stained by dyes with a high (basic) pH. *Neutrophils* comprise most of the total leukocytes in the bloodstream. They are polymorphonuclear cells, which serve as the primary human defense against invasive bacteria. Neutrophils migrate from the bloodstream into infected or inflamed tissue in response to chemotactic factors, such as IL-8 and breakdown products of complement (C3a and C5a). In this migration, a process termed *chemotaxis*, neutrophils reach the site of inflammation and then recognize (through the PRRs and PAMPs), adhere to, and phagocytose pathogens. In addition, complement and antibody can bind to specific epitopes on a pathogen (opsonize) and then bind to their corresponding receptors on neutrophils to phagocytize the pathogen. During phagocytosis, the engulfed pathogen is internalized within the phagocyte into a cytoplasmic lysosome. The neutrophil then releases its granular contents into lysosomes to form phagolysosomal granules, which generate the release of oxidative metabolites that destroy the engulfed pathogens.[17]

Eosinophils are also granulocytic cells involved in innate immunity and can migrate from the blood into the tissues. They play a less significant role in combating bacterial infections, but eosinophils play a major role against nonphagocytable multicellular pathogens, such as parasites. After activation via high-affinity receptor for IgE (ie, Fcε), eosinophils exocytose their granules causing the release of basic proteins or reactive oxygen species into the microenvironment, causing lysis of the parasite. In addition to Fcε receptors, eosinophils express lower levels of complement receptor 3 and Fcγ for IgG than neutrophils. The high affinity of eosinophils for IgE contributes to their role in the pathogenesis of allergies.[18]

Macrophages and *monocytes* are mononuclear cells capable of phagocytosis. Tissue macrophages arise from the migration of monocytes from the bloodstream into the tissues. Macrophages differ from monocytes in that they possess an increased number of Fc and complement receptors. Macrophages are found within specific tissues and are often called histiocytes. However, they are most often referred to by specialized names depending on the site where they are found (eg, Kupffer cells in the liver, osteoclasts in the bone, and microglial cells in the CNS).[19] The term reticuloendothelial system was commonly used to refer to phagocytic cells of the reticular connective tissue, but the preferred term is now the mononuclear phagocyte system.

② Despite the first description of Langerhans cells, a type of *dendritic cell* (DC) found in the skin in 1868, our current understanding of the biologic function of DCs did not develop until the last few decades. Before pathogen recognition, most DCs are in an immature/resting state with limited ability to activate T-lymphocytes, but they express numerous receptors (eg, Fc receptors of IgG and IgE, macrophage mannose receptor, and toll-like receptors) that enable rapid recognition and phagocytosis of multiple antigens. Following antigen recognition and particle engulfment, DCs become activated and greatly increase their expression of the MHC class II, B7-1/B7-2 (L/CD86), CD40, and adhesion molecules. In addition to phagocytosing pathogens in the innate immune system, macrophages and DCs act as APCs to stimulate the adaptive immune system. Macrophages and DCs perform this function by internalizing pathogens, digesting them into small peptide fragments, and then combining these antigenic fragments with MHC molecules, which move to the cell's surface and present peptides to the T-cell receptor (TCR) on the surface of a T-lymphocyte. The recognition of the antigen/MHC complex by the TCR is the first step in the activation of the T-lymphocyte (Fig. e106-3). B-lymphocytes can also act as APCs, which is important to the development of specific antibodies (Fig. e106-4).[19–21]

FIGURE e106-3

Induction of T-helper type 1 (TH1) response. (1) The APC, in this case a DC, engulfs the pathogen by any of numerous cell surface receptors (Fig. e106-2). After phagocytosis of the pathogen by the DC (A), the pathogen is digested into small peptides which becomes associated with major histocompatibility (MHC) class II within the endosome (B). Finally, the MHC class II molecule/peptide complex is expressed on the surface of the DC (C). The activated DC also secretes interleukin (IL)-12. (2) Naïve CD4+ T-lymphocyte activation requires the T-cell receptor (TCR) to recognize the antigenic peptide in association with MHC class II as well as the B7-1 (CD80) binding to CD28. The binding of CD2-CD58 and LFA-1 (CD11a/CD18) allows adherence between the T-lymphocyte and DC. Upon activation, the TH1 CD4+ T-lymphocyte secretes IL-2 and interferon (IFN)-γ and increases the production and expression of the IL-2 receptor (ICAM, intercellular adhesion molecule).

FIGURE e106-4

Induction of T-helper type 2 (TH2) response. (1A) A B-lymphocyte recognizes invading bacteria via its surface immunoglobulin (sIg). (1B) The bound bacteria are phagocytosed into an endosome, where the bacteria are broken down into small peptide fragments. (1C) The small peptide fragments are placed within MHC class II molecules and transported to the surface of the B-lymphocyte for antigen presentation to a CD4+ T-lymphocyte. (2) CD4+ T-lymphocyte recognition requires antigen recognition within the MHC class II peptide groove by the T-cell receptor (TCR) and a secondary signal from B7-2 from the antigen-presenting cell, in this case a B-lymphocyte, binding to CD28 on the T-lymphocyte. When both signals are delivered, the CD4+ T-lymphocyte becomes activated. In the TH2 environment (see the text), the naive CD4+ T-lymphocyte develops into a TH2 subtype and secretes interleukin (IL)-4, IL-5, IL-6, IL-10, and IL-13, which promotes a TH2 response. (3) In the presence of these cytokines plus antigen binding to the sIg, the B-lymphocyte becomes activated. The activated B-lymphocyte becomes a plasma cell (4), which produces and secretes immunoglobulin or becomes a memory B-lymphocyte (5). A minority of B-lymphocytes become memory B-lymphocytes.

Mast cells and *basophils* act primarily by releasing inflammatory mediators. Mast cells are tissue cells predominately associated with IgE-mediated inflammation. They are especially abundant in the skin, lungs, nasal mucosa, and connective tissue. Granules within the mast cells contain large amounts of preformed mediators that include histamine, heparin, and serotonin. Mast cells can also phagocytize, destroy, and present bacterial antigens to T-lymphocytes.[20] Basophils are similar to mast cells because they contain granules filled with histamine, but they are typically found circulating in the blood and are not found in connective tissue. Like mast cells, basophils also express high-affinity IgE Fc receptors (Fcε). IgE-mediated anaphylaxis (type I hypersensitivity [Chapter e108]) is caused by the degranulation and the release of preformed mediators upon stimulation of mast cells or basophils by an allergen binding to IgE bound to the Fcε receptor on their cell surface.[21]

Soluble Mediators of the Innate Immune System

Soluble mediators of innate immunity involve proteins that include the complement system, mannose-binding lectin, antimicrobial peptides, and C-reactive protein (CRP).[11] The complement system consists of more than 30 proteins in the plasma and on cell surfaces that play a key role in immune defense. The four major functions of the complement system include: (a) lysis of certain microorganisms and cells; (b) stimulation of chemotaxis of phagocytic cells; (c) coating or opsonization of foreign pathogens, which allows phagocytosis of the pathogen by leukocytes expressing complement receptors; and (d) clearance of immune complexes. Complement factors (C3a, C5a) also act as chemotactic factors for phagocytic cells.[22] Two different pathways stimulate the complement cascade. In the *classical pathway*, the antibody binds to its target antigen and activates the first component of complement (C1), thereby initiating the complement cascade. The *alternative complement pathway* relies on the inability of microorganisms to clear spontaneously produced C3b, the active form of the third complement protein, from their surface. Patients with hereditary deficiencies of complement have recurrent bacterial infections or immune complex disease because C3b plays a central role in opsonizing bacteria and clearing immune complexes.

Both mannan-binding lectin and CRP are acute-phase reactants produced by the liver during the early stages of an infection. They act as opsonins by binding to infectious pathogens that serve as an intermediate by binding to their respective receptors on phagocytes. Mannan-binding lectin binds to mannose-rich glycoconjugates on microorganisms, while CRP binds to phosphorylcholine on bacterial surfaces.[11,22]

The chemokine system consists of a group of small polypeptides and their receptors. *Chemokines* play an essential role in linking the innate and adaptive immune response by orchestrating leukocyte trafficking. Chemokines possess four conserved cysteines. Based on the positions of the cysteines, almost all chemokines fall into one of the two categories: (a) CC group in which the conserved cysteines are contiguous or (b) CXC subgroup in which the cysteines are separated by some other amino acid (X). As with all ligand-receptor interactions, a cell can only respond to a chemokine if the cell possesses a receptor that recognizes the chemokine. Chemokine receptors are unique in that they traverse the membrane seven times. CC receptors (CCR) and CXC receptors (CXCR) bind CC ligands (CCL) and CXC ligands (CXCL), respectively (Table e106-4).

TABLE e106-4

Common Chemokines

Receptor	Cell Expression	Ligand
CCR1	Immature DC	MIP-1α, MIP-1β, MCP-2, RANTES
CCR3	Eosinophils, basophils	Eotaxin-1, eotaxin-2, eotaxin-3, MCP-4
CCR6	Immature DC	Exodus-1
CCR7	Activated DC	CCL21 (SLC), CCL19 (ELC)
CXCR1/2	Neutrophils	IL-8
CXCR3	Natural killer cells, activated T-lymphocytes	IP-10

DC, dendritic cell; ELC, EBI1 ligand chemokine; MCP, monocyte chemoattractant protein; RANTES, regulated upon activation normal T-lymphocyte expressed and secreted; SLC, secondary lymphoid tissue chemokine.

Binding of infectious pathogens to PRRs stimulates the release of chemokines such as macrophage inflammatory protein (MIP)-1α, MIP-1β, MIP-3α, and IP-10 from macrophages and DCs embedded in the tissues. These chemokines attract more immature DCs to the site of inflammation/infection. Immature DCs constitutively express CCR1, CCR5, and CCR6. The interaction between PRRs on the DC to the infectious pathogen causes the activation and maturation of the DC. After activation, DCs downregulate the expression of CCR1, CCR5, and CCR6 and upregulate the expression of CCR7. This switch in chemokine-receptor expression results in the antigen-loaded DC leaving the tissue and migrating toward the lymph nodes.[23]

Naturally occurring antimicrobial peptides include α-defensins, β-defensins, and cathelicidins. These peptides exhibit antibacterial, antifungal, and antiviral activity. Human antimicrobial peptides range from 29 to 37 amino acid residues in length. Neutrophils are rich sources of both α- and β-defensins as well as cathelicidins. Other sources of the human antimicrobial peptides include keratinocytes, Paneth cells of the intestinal and genital tracts, and epithelial cells of the pancreas and the kidney. These peptides can be induced at sites of inflammation or can be constitutively produced. The clinical interest in human antimicrobial peptides centers on their broad-spectrum activity and their rapid onset of killing. They are believed to work by disrupting microbial membranes. An active area of research is how these peptides discriminate between microbial and host membranes.[24]

Adaptive Immune System

The body will generally employ innate and adaptive immune responses to rapidly kill foreign pathogens.[11] The greatest difference between innate and adaptive immune responses is specificity and memory, characterized by antigen-specific receptors located on the surface of B (sIg) and T-lymphocytes (TCR).[13] Cells that mediate the adaptive immune response also secrete cytokines to further amplify the innate immune response. The adaptive immune response can evolve with each subsequent infection whereas the innate response stays the same with each infection. During B- and T-lymphocyte development, an individual B- or T-lymphocyte rearranges its immunoglobulin and TCR genes, respectively, to produce a unique immunoglobulin or TCR. This DNA rearrangement generates enough B- or T-lymphocytes to recognize an estimated 1012 and 1010 antigens, respectively.

The adaptive immune response can be divided into two major arms: humoral and cellular responses. The humoral response is so named because it was discovered that the factors that provided the immune protection could be found in the “humor” or fluids (eg, serum, plasma, lymph) and generally refers to antibody responses. To generate a good antibody response, T-lymphocytes of the T-helper cell phenotype are necessary. B-lymphocytes activated in this way can differentiate into plasma cells and secrete antibodies or they differentiate into memory B-cells that are specific for the pathogen that reacted with its sIg.

Cells of the Adaptive Immune System

T-lymphocytes constitute the cell-mediated arm of the adaptive system. The immune protection provided by T-lymphocytes cannot be transferred by fluids alone. Rather, it is essential to actually have T-lymphocytes present, thus the term cell-mediated immunity. T-lymphocytes are specially tailored to defend against infections that are intracellular, such as viral infections, whereas B-lymphocytes secrete antibodies that can neutralize pathogens prior to their entry into host cells.

③ The role of the T-lymphocyte is to respond to various pathogens extracellularly (CD4+ T-helper cells and MHC Class II) or intracellularly (CD8+ T-cytotoxic cells and MHC Class I). T-lymphocytes use a specific antigen receptor, the TCR, to propagate the immune response. The TCR is comprised of two chains, with each chain having a variable and a constant region. The variation of the amino acid sequence within the variable domain of the TCR gives the cell its unique antigen specificity. Linked to the TCR is a complex of single chains known as the CD3 complex.[11,21]

The MHC is a cluster of genes found on chromosome 6 in humans, also known as the human leukocyte antigen (HLA) complex, that is converted to proteins used by the immune system to distinguish self from nonself and provides a so-called immunologic “fingerprint.” The MHC complex is divided into three different classes: I, II, and III. There are six MHC class I genes (A, B, C, E, F, and G) of which only A, B, and C are considered major. These molecules can be found on all nucleated cells within the body and on platelets. MHC class I antigens are not found on mature red blood cells. Molecules encoded by class II MHC genes include DP, DQ, and DR. The expression of these molecules is more restricted and can be found primarily on APCs, such as macrophages, DCs, and B-lymphocytes. The class III HLA antigens encode for soluble factors, complement, and tumor necrosis factors (D-80s).[25] For a CD4+ T-lymphocyte to become activated, it must recognize the antigenic peptide in association with MHC class II (see Figs. e106-3 and e106-4).

CD8+ T-lymphocytes recognize antigenic peptide in association with class I MHC molecules. Class I MHC molecules generally form complexes with endogenous peptides from within the cell, such as those derived from viruses. In contrast, Class II MHC molecules generally form complexes with exogenous peptides from antigen that has been phagocytized and digested, such as bacterial peptides (see Fig. e106-3). Thus, the MHC Class I and CD8+ T-cell interaction is a sensing system by which the immune system is constantly checking the nucleated cells of the body for what is happening inside the cells of the body.[25,26] DCs, and to a lesser extent macrophages, demonstrate the unique capacity to direct exogenous antigens toward MHC class I molecules, a process termed cross-presentation.[27] In contrast, the MHC class II and CD4+ T-cell interaction is a sensing system by which the immune system is constantly checking for what is happening outside of our cells.

Naïve T-lymphocytes are cells that have not been previously exposed to an antigen specific for their TCR. These cells require two signals for activation. The first signal for activation involves the T-lymphocyte recognizing both the processed antigen and the MHC molecule complex. The second signal involves the interaction of the B7-1 (CD80) or B7-2 (CD86) molecule on the APC with the CD28 molecule on the surface of the T-lymphocyte (see Figs. e106-3 and e106-4). Without the second signal, the naïve T-lymphocyte becomes anergic or inactive. Memory T-lymphocytes are less dependent on the second signal than are naïve T-lymphocytes. CD28 is expressed on both resting and activated T-lymphocytes. After the two activation signals, a message is sent through the TCR to the CD3 complex into the cell. Then calcium influx occurs, resulting in activation of the T-lymphocyte. Activated CD4+ T-lymphocytes begin to express the high-affinity interleukin 2 (IL-2) receptor and release multiple soluble factors (eg, IL-2) to stimulate T-lymphocytes and other cells of the immune system (see Fig. e106-3). Autocrine stimulation by IL-2 leads to the proliferation of the activated T-lymphocyte.

In addition to activation pathways, T-lymphocytes can also express inhibitory receptors on their cell surface. One example is cytotoxic T-lymphocyte-associated protein 4 (CTLA-4), which also binds B7, and is only expressed on activated T-lymphocytes. When B7 binds to CTLA-4 on an activated T-lymphocyte, an inhibitory signal is sent to the T-lymphocyte, thereby modulating the T-lymphocyte response.[28] The exact mechanism by which CTLA-4 binding inhibits T-lymphocyte activity is not fully understood.

Cell surface markers delineate the functional activity of T-lymphocyte populations. All T-lymphocytes express the CD3 protein. Typically, T-lymphocytes are further divided into helper cells (CD4+), suppressor cells (CD8+), and cytotoxic cells (CD8+). Each subclass plays a distinct role in the cell-mediated immune response. Naïve T-lymphocytes express CD45RA, a high-molecular-weight isoform of CD45, while memory T-lymphocytes express CD45RO, a lower-molecular-weight isoform of CD45.[29] The primary role of CD4+ cells is to stimulate other cells in the immune response. Functionally, CD4+ cells can be divided into T-helper type 1 (TH1), T-helper type 2 (TH2), TH17, T follicular helper (THFH), and T-regulatory (Tregs). This functional system was first described in mice. TH1 cells secrete IL-2 and γ-interferon and stimulate CD8+ cytotoxic cells while TH2 cells secrete IL-4, IL-5, and IL-10 and stimulate B-lymphocyte production of antibodies against extracellular pathogens.[30] Multiple factors determine whether a naïve CD4+ T-lymphocyte develops into a TH1 or a TH2 cell. The cytokine microenvironment plays an important role in this development. IL-12 secreted by the APCs promotes TH1 while IL-4 promotes TH2 development. Other factors that promote TH1 development include B7-1 (CD80), high affinity of the TCR for the antigen, γ- interferon, and α-interferon. Factors that promote TH2 development include B7-2 (CD86), low affinity of the TCR for the antigen, IL-10, and IL-1.[31] THFH also promote B-lymphocyte activation and play a crucial role in the generation of memory B-lymphocytes which leads to long-lived antibody responses.[32] The TH17 subset was discovered because of selective production of IL-17 and plays an important role in immunity in mucosal tissues and in the pathogenesis of multiple inflammatory and autoimmune disorders.[33]

CD8+ T-lymphocytes recognize antigen in association with MHC class I. CD8+ cytotoxic cells are instrumental in killing cells recognized as foreign, such as those that have become infected by a virus. CD8+ cytotoxic T-lymphocytes play an important role in the eradication of tumor cells, which often express mutated or altered forms of self-antigens. Cytotoxic T-lymphocytes are also responsible for the rejection of transplanted organs and for the phenomenon known as graft-versus-host disease.[21] Some T-lymphocytes suppress the immune responses and maintain self-tolerance, but it is not clear whether this subset is CD8+. These cells are not CD8+ T-lymphocytes but are CD4+, CD25+ T-lymphocytes. The preferred term for these suppressive T-lymphocytes is regulatory T-lymphocytes.[34]

Our understanding of how CD8+ T-lymphocytes are activated is constantly evolving. The traditional model involves the interaction of a CD8+ T-lymphocyte with an APC, typically a DC. More potent activation of CD8+ T-lymphocyte may result from the interaction of an APC, typically a DC, a CD4+ helper lymphocyte (TH1), and a CD8+ T-lymphocyte (Fig. e106-5A). This model of CD8+ cytotoxic T-lymphocyte activation requires close proximity of two antigen-specific T-lymphocytes (the CD4+ and the CD8+ T-lymphocytes). In addition, CD8+ cytotoxic T-lymphocyte activation can occur in the absence of direct interaction with CD4+ T-lymphocytes. CD4+ T-lymphocytes can activate APCs through CD40; this interaction primes the APC to fully activate CD8+ cytotoxic T-lymphocytes (Fig. e106-5B).[35] It is important to remember that the classification of CD4+ lymphocytes as T-helper lymphocytes and CD8+ lymphocytes as T-cytotoxic lymphocytes is not absolute. Some CD8+ T-lymphocytes secrete cytokines similar to a T-helper lymphocyte and some CD4+ T-lymphocytes can act as cytotoxic cells.

FIGURE e106-5

In the classic model of CD8+ T-lymphocyte activation (A), CD4+ and CD8+ T-lymphocytes recognize antigen on the same DC. In the presence of interleukin (IL)-2 from the activated CD4+ T-lymphocyte and the recognition of antigen in association with major histocompatibility complex (MHC) class I, the CD8+ T-lymphocyte becomes activated. In the new model (B), activated CD4+ T-lymphocytes activate DCs via CD40 ligand binding to CD40. The activated DC then migrates through the tissues to present antigen to CD8+ T-lymphocytes. If recognition via the T-cell receptor (TCR) on the CD8+ T-lymphocyte occurs, the DC can fully activate the CD8+ T-lymphocyte without the presence of CD4+ T-lymphocytes.

Unlike neutrophils and macrophages, cytotoxic T-lymphocytes are unable to ingest their targets. They destroy target cells by two different mechanisms: the *perforin system* and the *Fas ligand pathway*. After recognition by the cytotoxic T-lymphocyte, cytoplasmic granules containing perforins and granzymes are rapidly oriented toward the target cell and the granule contents are released into the intracellular space. Like the membrane attack complex formed after complement activation, perforins form a pore in the target cell membrane. Besides a direct cytotoxic effect on the target cell, the pores allow the granzymes to penetrate into the target cell and induce apoptosis. The second mechanism of cytotoxicity involves the binding of Fas ligand (FasL) on the cytotoxic T-lymphocyte to the Fas receptor on the target cell. The FasL is predominately expressed on CD8+

cytotoxic T-lymphocytes and natural killer (NK) cells, and its expression increases after activation. When the Fas receptor on the target cell is bound by FasL expressed by the CD8+ cytotoxic T-lymphocyte, the target cell receives a strong signal inducing it to undergo apoptosis (ie, commit suicide).[36] After destroying the target cell by either mechanism, the cytotoxic T-lymphocyte detaches from the targetcell and attacks other targets.[37]

A B-lymphocyte recognizes antigen via its antibody or immunoglobulin (sIg) located on its cell surface (see Fig. e106-4). The sIg can recognize an intact pathogen, such as bacteria, and present antigen to T-lymphocytes (ie, acting as APC). However, another major function of B-lymphocytes is to differentiate into a plasma cell to produce antibody specific for the invading pathogen, a process that first requires activation of the B-lymphocyte. The activation of B-lymphocytes also requires two steps: (a) recognition of antigen via the sIg; and (b) the presence of B-lymphocyte growth factors (IL-4, 5, and 6) secreted by activated CD4+ T-lymphocytes. Once activated, the B-lymphocyte becomes a plasma cell, a differentiated cell capable of producing and secreting antibodies and then dying. Some activated B-lymphocytes do not differentiate into plasma cells, but rather form a pool of memory B-cells. The memory B-cells will respond to subsequent encounters with the pathogen, generating a quicker and more vigorous response to the pathogen. Some B-lymphocytes can become activated without help from T-lymphocytes, but these responses are generally weak and do not invoke memory.[11,21]

NK cells, often referred to as large granular lymphocytes, are defined functionally by their ability to lyse target cells without prior sensitization and without restriction by MHC. NK cells recognize target cells by two mechanisms. First, NK cells express an IgG Fc receptor, CD16, that allows recognition of IgG-coated cells. Second, NK cells express killer-activating and killer-inhibiting receptors. The killer-activating receptors recognize multiple targets on normal cells, but the binding of MHC class I to the killer-inhibitor receptor blocks the release of perforins and granzymes. Therefore, cells (eg, tumor cells, virally infected cells) that downregulate MHC class I expression are susceptible to NK cell cytolysis. NK cells play important roles in the surveillance and the destruction of tumors and virally infected host cells, and in the regulation of hematopoiesis.[11,38]

The immune system employs several mechanisms to downregulate responses to prevent autoimmune diseases. Many of these mechanisms are directed at T-lymphocyte activation. After activation (about 2 days), T-lymphocytes express CTLA-4 (a second ligand for B7 [CD152]). As previously discussed, when CTLA-4 binds B7, T-lymphocyte activity is inhibited. Another mechanism of T-lymphocyte inhibition is the programmed cell death 1 (PD-1) system. Once a T-lymphocyte is activated, it expresses the PD-1 receptor. The PD-1 receptor can bind to two separate ligands, known as PD-L1 and PD-L2. When bound to its ligand, PD-1 inhibits antigen receptor signaling in T-lymphocytes, resulting in decreased production of proinflammatory cytokines by the T-lymphocyte.[39] Interestingly, the same Fas/FasL system used by CD8+ cytotoxic T-lymphocytes to destroy their targets is also a mechanism that can inhibit T-lymphocytes. Once T-lymphocytes become activated, they express Fas receptors on their cell surfaces. If the Fas receptor on a T-lymphocyte is bound by FasL, the T-lymphocyte receives a signal inducing it to undergo apoptosis. Certain tissues, such as the testis, retina, and some types of cancer cells use the Fas system to protect themselves from harmful immune responses. These tissues constitutively express the FasL, which protects them from activated T-lymphocytes.[40] Another means of modulating T-lymphocyte responses is through a functional subset of CD4+ lymphocytes: Tregs. Tregs are antigen specific and require contact between the Tregs and the target T-lymphocyte to exert their inhibitory effect. Tregs can downregulate T-lymphocyte responses by secreting transforming growth factor-β and IL-10.[34]

Soluble Mediators of the Adaptive Immune Response

Antibodies

④ When the binding of a specific antigen to the surface immunoglobulin receptor of B-lymphocytes occurs, the B-lymphocyte matures into a plasma cell and produces large quantities of antibodies that have the ability to bind to the inciting antigen. The secreted antibodies may be of five different isotypes: IgA, IgD, IgE, IgG, and IgM. On primary exposure to a given pathogen, the plasma cell will secrete IgM, followed by an eventual switch to predominately IgG. Upon a second exposure to the same antigen, the memory B-lymphocytes will predominately produce IgG. Isotype switching from IgM to IgG, IgA, or IgE is controlled by T-lymphocytes.

An antibody or immunoglobulin is a glycoprotein comprised of two different chains, heavy and light (Fig. e106-6). The basic structure of every immunoglobulin consists of four peptide chains: two identical heavy chains and two identical light chains held together by disulfide bonds. The basic structure of the antibody is a Y-shaped figure. Each arm of the Y is formed by the linkage of the end of the light chain to its heavy chain partner. These arms contain the portions described as the *fragments of antigen binding (Fab fragments)*. The stem of the Y contains the heavy chains, which comprise the *fragment crystallizable (Fc fragment)* portion of the antibody. It is within the Fc portion that complement is activated once the antibody has bound its target. Likewise, it is the Fc portion of the antibody that is recognized by Fc receptors on the surface of phagocytes (see Fig. e106-2). The amino acid composition of the same isotype is homogenous except in the variable regions of the light (*V*L) and heavy chains (*V*H). The variation in amino acid composition of the variable region gives the antibody its unique specificity (see Fig. e106-6).

FIGURE e106-6

Schematic diagram of the structure of the IgG molecule. IgG molecule consists of 2 heavy (H) and 2 light (L) chains covalently linked by disulfide bonds. Each chain is composed of variable (*V*) and constant (C) regions. A light chain consists of 1 variable (*V*L) and 1 constant (*C*L) region. Heavy chains consist of 1 variable (*V*H) and 3 or 4 constant (*C*H) regions, depending on the isotype. The variable regions (*V*L and *V*H) compose the antigen-binding region of the IgG molecule, or fragment antigen binding (Fab). The constant regions provide the structure to the IgG molecule and bind to the first component of complement (CH2) and to Fc receptors via the Fc portion of the molecule (CH3).

IgG, the most prevalent antibody class, comprises about 80% of serum immunoglobulins. IgG is usually the second isotype of antibody produced during an initial humoral immune response. IgG is the only isotype of antibody that can cross the placenta. Therefore, early maternal humoral protection of neonates is primarily due to maternal IgG that has crossed the placenta in utero.

Four different subclasses of IgG have been described: IgG1, IgG2, IgG3, and IgG4. These subclasses differ slightly in their constant amino acid sequences. IgG1 constitutes the majority (60%) of the subclasses. Different subclasses recognize different types of antigens. IgG1 and IgG3 primarily recognize protein antigens, while IgG2 and IgG4 commonly bind to carbohydrate antigens. Another difference in the subclasses is their ability to activate complement with IgG3 and IgG1 being the most efficient, while IgG4 is unable to activate the complement system.

IgM can be found on the surface of B-lymphocytes (sIg) as a monomeric Y-shaped structure. In contrast, secreted IgM is a pentamer in which five of the monomers are joined together by a joining chain (J-chain). IgM is the first class of antibodies produced following initial exposure to an antigen. Because the pentameric form of IgM has no Fc portions exposed, phagocytic cells cannot bind pathogens opsonized by IgM. However, IgM is an excellent activator of the complement cascade by the classic pathway.

IgA is found primarily in the fluid secretions of the body: tears, saliva, nasal fluids; and also in the GI, genitourinary, and respiratory tracts. IgA functions by preventing pathogens from adhering to and infecting the epithelial cells at these sites. IgA is also secreted in a nursing mother’s breast milk; IgG and IgM are also secreted but in lower concentrations. In bodily secretions, IgA is in a dimeric form in which a J-chain and a secretory chain hold two monomers together. The dimeric form is resistant to proteolysis in mucosal secretions.

IgD is the least understood isotype. IgD is found on the surface of B-lymphocytes at different stages of maturation and may be involved in the differentiation of these cells. The main function of circulating IgD has not yet been determined. However, mice treated with exogenous anti-IgD antibodies display a marked increase in immunoreactivity and secretion of all types of immunoglobulins and several T-cell specific cytokines. High levels of anti-IgD autoantibodies of various subtypes have also been observed in most autoimmune diseases with frequencies of more than 50%, suggesting that IgD may play an important role in the etiology of these diseases.[41]

IgE is the least common of the serum antibody isotypes. Most of the IgE in the body is bound to the IgE Fc receptors on mast cells. When the IgE on the surface of mast cells binds antigen, it causes the mast cell to release various inflammatory substances (eg, histamine). The overall effect is stimulation of inflammation. The major function of IgE antibody is to eliminate parasites, but because developed countries of the world have few, if any parasites, the response has shifted and it now plays an important role in allergies. Hay fever is an example of allergic reactions primarily due to antigen binding to IgE.

Cytokines

Cytokines are soluble factors released or secreted by cells. These proteins affect the activity of other cells (paracrine) or the secreting cell itself (autocrine). For example, activated CD4+ T-lymphocytes secrete IL-2, which further activates the secreting cells, CD8+ T-lymphocytes, and NK cells. Research has shown that many cytokines have a broad spectrum of effects depending on their concentration, the presence of other factors, and the target cell (Table e106-5). New cytokine families and their roles in disease processes are being discovered regularly. Cytokines provide communication between the divisions of the immune system. Cytokines produced from APCs generally promote chemotaxis of other cells and induce a state of inflammation.[38] Cytokines can also prevent the activation or response of immunologic cells. For example, IL-10 is an anti- inflammatory cytokine produced in the respiratory tract to prevent IgE synthesis and activation of eosinophils when exposed to benign inhaled particles.[38] Cytokines do not act alone in vivo, but in combination with other cytokines. For example, activated CD4+ T-lymphocytes secrete both IL-2 and interferon-γ, which are synergistic in activating NK cells. As shown in Tables e106-1 and e106-5, cytokines are broadly classified as regulatory or hematopoietic growth factors.[21,42–47] This classification does not describe all their activities. For example, GM-CSF released by activated T-lymphocytes not only acts as a hematopoietic growth factor, but it also activates circulating granulocytes and APCs to phagocytize foreign pathogens.

TABLE e106-5

Regulatory Cytokines

Cytokines	Sources	Principal Effects
IL-1	Macrophages, fibroblasts, endothelial cells	Activation of T and B-lymphocytes, hematopoietic growth factor, and induction of inflammatory events
IL-2	CD4+ T-lymphocytes (TH1 subset)	Activation of T-lymphocytes, B-lymphocytes, and NK cells
IL-4	CD4+ T-lymphocytes (TH2 subset), mast cells, basophils, eosinophil s	B- and T-lymphocytes growth factor, activation of macrophages, promotes IgE production, proliferation of bone marrow precursors
IL-5	CD4+ T-lymphocytes (TH2 subset), mast cells	Activation of B-lymphocytes and eosinophils, promotes IgE production
IL-6	CD4+ T-lymphocytes (TH2 subset), macrophages, mast cells, fibroblasts	T- and B-lymphocytes growth factor, hematopoietic growth factor, augments inflammation
IL-8	T-lymphocytes, monocytes, endothelial cells, fibroblasts	Neutrophil, basophil, and T-lymphocytes chemotaxis
IL-10	T- and B-lymphocytes, macrophages	Cytokine synthesis inhibitory factor, growth of mast cells
IL-12	Macrophages, neutrophils, dendritic cells	Induce TH1 cells, ↑ NK cell activity, ↑ generation of cytotoxic T-lymphocytes

IL-13	Activated T-lymphocytes	Proliferation of B-lymphocytes, suppression of proinflammatory cytokines, directs IgE isotype switching
IL-14	T-lymphocytes	Induces B-lymphocytes proliferation, inhibits secretion of Igs
IL-15	Macrophages, fibroblasts, dendritic cells, epithelial cells	T-lymphocytes proliferation and activation of NK cells
IL-16	$CD8^+$ T-lymphocytes, epithelial cells	Chemoattractant for CD4+ T-lymphocytes and eosinophils; stimulation of secondary cytokine secretion from and proliferation of CD4+ T-lymphocytes
IL-17	CD4+ T-lymphocytes (TH17 subset)	Proinflammatory cytokine that promotes the neutrophil expansion and accumulation in the tissues
IL-18	Macrophages	Induces γ-interferon production
IL-23	Macrophages	Inflammatory macrophages express IL-23R and are activated by IL-23 to produce IL-1, TNF-α, and IL-23 itself
IL-28 and -29[a]	Antigen-presenting cells, but proposed that all nucleated cells may produce	Alternative to α/β interferons to provide immunity against viral infections by inhibiting viral replication
IL-31	Activated T-lymphocytes	Involved in the recruitment of PMNs, monocytes, and T-cells to the site of inflammation
IL-32	NK-cells, T-lymphocytes, epithelial cells	Induces proinflammatory cytokines including TNF-α and IL-8
IL-35	CD4+ T-lymphocytes (Treg subset)	T-cell suppression
TNF-α	Macrophages, NK cells, T-lymphocytes, B-lymphocytes, mast cells	Activation of neutrophils, endothelial cells, lymphocytes, and liver cells to produce acute phase proteins
TNF-β	T-lymphocytes	Tumoricidal
IFN-α	Monocytes, other cells	Antiviral, activation of NK cells and macrophages, upregulation MHC class I
IFN-γ	T-lymphocytes, NK cells	Activation of macrophages, NK cells, upregulation of MHC class I and II

[a] Also known as the new type III IFN-λ family.

The division of the immune system into the two functional groups does not imply that the divisions do not interact with each other. Both soluble mediators (eg, complement, antibody, and cytokines) and cells (eg, neutrophils, macrophages, DCs, T-lymphocytes, and B-lymphocytes) are needed to generate a vigorous immune response. The innate system will usually respond first. DCs, macrophages, and neutrophils in the tissues will recognize pathogens via surface receptors (see Fig. e106-2). To amplify the immune response, the APCs will present antigen to CD4+ T-lymphocytes (see Figs. e106-3 and e106-4). The activated CD4+ T-lymphocytes will secrete cytokines to activate B-lymphocytes, CD8+ T-lymphocytes, NK cells, macrophages, and neutrophils. The next section of the chapter discusses the evaluation of the immune system.

DISEASES OF THE IMMUNE SYSTEM

Although this chapter is not intended to detail the diseases of the immune system, it is necessary to review the terminology and provide specific examples of diseases of the immune system to understand the role of monitoring and possible intervention with pharmacotherapy. Diseases that impair the physical defense component of the immune system are often not considered as diseases of the immune system, but loss of normal physical defenses can compromise the immune response and result in infectious sequelae. For example, in cystic fibrosis, altered chloride transport results in thick respiratory secretions, which leads to colonization of the airways by pathogens and frequent respiratory infections. Primary immunodeficiency diseases are those characterized by either a congenital inability to produce components of the immune system (ie, severe combined immunodeficiency or hypogammaglobulinemia) or acquired, as seen with HIV infection. Autoimmune diseases result from a dysregulation of a component or a combination of components of the immune system (eg, rheumatoid arthritis, systemic lupus erythematosus [SLE]).[48] Autoimmune diseases are often characterized by the production of autoantibodies against a particular host structure that is critical for normal function, the loss of self-tolerance to otherwise healthy tissues, or the loss of tolerance or anergy to a ubiquitous antigen (ie, gluten in celiac sprue).[44] Often medications that suppress the immune system are necessary to control symptoms and halt autoimmune disease progression. Administration of immunosuppressive medications in the setting of autoimmune diseases or organ transplantation may reduce disease symptoms, but may also reduce the host's ability to fight off infection or cancer. Exogenous regulation of the immune system must be done carefully, and we must continue to discover new methods for the appropriate evaluation of immune responses.

EVALUATION OF IMMUNE FUNCTION

Assessment of a patient's immune function requires knowledge and understanding of multiple components including mechanical defenses, cell phenotypes and cell numbers, and soluble components. Recent developments have allowed immunologists to better understand the role of the immune response in many diseases. This is important because the upregulation and downregulation of immune responses are necessary to treat various disease states. Therefore, pharmacotherapeutic considerations must balance the risk of disrupting normal immunologic homeostasis. Improvements in immune monitoring are necessary for the goal of patient-specific immunologic pharmacotherapy. Despite technological advances, careful patient evaluations are required to accurately assess the structure and function of the immune system. Specific methods for assessment of patient immune status are discussed later.

Innate Immunity: Evaluation of Mechanical Immunodefenses

As discussed earlier, the mechanical aspects of host defense are extremely important in protection from infection; therefore, assessment of mechanical defenses is critical. Much of the assessment of mechanical immunodefense is accomplished by recognition of situations where it may be compromised. Careful patient examination usually reveals the extent of compromise and laboratory tests are generally not necessary for evaluation of this component. To assess the extent of compromise in mechanical immunodefenses, the clinician should carefully examine the patient and identify the specific types of risks present. Specific examples of altered mechanical defenses are listed in Table e106-6.

TABLE e106-6

Examples of Alteration in Mechanical Immunodefenses That Result in Impaired Immune Status

Reduced gastric pH
Achlorhydria
Use of histamine-2 blockers and proton pump inhibitors
Patients with acquired immunodeficiency syndrome
Break in skin barrier
Burns
Surgical incision
Penetrating trauma
Vascular access devices
Impaired mucociliary function of the lungs
Smoking
Impaired esophageal or epiglottal function
Endotracheal intubation
Stroke
Recumbent position
Altered urine flow
Urinary stones
Anatomic deformities obstructing flow
Bladder catheter
Anatomic alterations of the heart resulting in turbulent blood flow and endocarditis

Innate and Adaptive Immunity: Gross Evaluation of Cellular Components

A major aspect of the assessment of immune function relates to the cells of the immune system. Assessment of cells in the clinical setting includes the determination of cell type and cell number or function. Determination of the cell types and numbers is generally performed first because of the ease of obtaining these results and the common correlation with the clinical situation.

To quickly screen cell numbers, a *white blood cell* (*WBC*) *count* with differential is performed. Normal cell counts are shown in Table e106-7.[49] This simple test often steers the differential diagnosis. In interpreting a WBC with differential, the clinician must consider several factors. A normal cell count does not mean that a leukocyte disorder does not exist. For example, in chronic granulomatous disease, a child may have a normal neutrophil count, but the neutrophils are unable to destroy bacteria. Second, a differential is reported as a percentage of the WBCs. Therefore, one must also assess both the absolute number and the percentage of white cell subtypes. For example, a patient admitted to the hospital with pneumonia has an elevated WBC (15,000 cells/mm^3 [15 × 10^9/L]) with a manual differential of 70% segs, 10% bands, 15% lymphocytes, and 5% monocytes. The WBC is predominately neutrophils; segs or mature neutrophils (70%); and bands or immature neutrophils (10%). The percentage of lymphocytes is low at 15% (see Table e106-7), but the absolute number of lymphocytes is actually normal, 2,250 cells/mm^3 (15,000 cells/mm^3 × 0.15) (2.25 × 10^9/L [or 15 × 10^9/L × 0.15]). A third factor to consider is that most lymphocytes are in secondary lymphoid organs (eg, lymph nodes and spleen), and changes in peripheral blood lymphocytes do not always mirror changes in the secondary lymphoid organs. Additionally, most granulocytes, macrophages, and mast cells are also in the tissues, not the bloodstream.

TABLE e106-7

Leukocyte Counts in Adults

Cell	Absolute Count (Range)[a]	Percentage (Range)[b]
White blood cells	7,500 (4,500-11,000)	100
Neutrophils	4,500 (2,300-7,700)	60 (50-70)
Eosinophils	20 (0-45)	3 (0-5)
Basophils	4 (0-20)	1 (0-2)
Monocytes	30 (0-80)	4 (0-10)
Lymphocytes	210 (160-240)	32 (28-39)
T-lymphocytes	140 (110-170)	72 (67-76)[b]
CD4[a]	80 (70-110)	42 (38-46)[b]
CD8[a]	70 (50-90)	35 (31-40)[b]
B-lymphocytes	30 (20-40)	13 (11-16)[b]
Natural killer cells	30 (20-40)	14 (10-19)[b]
CD4/CD8 ratio	1.2 (1-1.5)	

[a] Cell counts are expressed as cells/mm^3 or × 10^6/L.

[b] Percentage of lymphocyte subpopulations expressed as percentage of total lymphocyte population. For expression in SI units multiply each number by 0.01 to give the corresponding fraction.

To assess the numbers of granulocytes (neutrophils, basophils, and eosinophils) and monocytes, one uses a WBC with differential. An increased WBC count with immature neutrophils (eg, bands, metamyelocytes, myelocytes, and promyelocytes) in the peripheral blood is called a “shift to the left,” and is abnormal. It most often indicates a bacterial infection, but can also indicate trauma or leukemia. It has long been recognized that the lower the absolute neutrophil count, the greater the risk of infection. Drugs (eg, chemotherapy) and diseases (eg, collagen vascular disorders) may lower the neutrophil count and make the patient more susceptible to infections. Patients with a neutrophil count of less than 1,500 cells/mm^3 (1.5×10^9/L) are considered to have neutropenia. Functional analysis of these cell types is rarely done in routine clinical practice. Patients with suspected functional deficits in these cell types are generally referred to tertiary medical centers for evaluation and treatment.

A routine WBC with differential can determine the total lymphocyte count. Lymphocyte populations with different functions or in various stages of activation can be characterized based on their cell surface markers. These cell surface markers are known as clusters of differentiation (CD). The CD is usually a protein or glycoprotein on the cell surface. CD followed by a number designates the marker. Hundreds of monoclonal antibodies have been designed to recognize these cell surface markers. Monoclonal antibodies can be labeled with a fluorescent marker. The labeled monoclonal antibodies are then incubated with the patient’s cells. The antibodies will recognize and bind to the cells expressing the CD of interest, and the cells are then counted with flow cytometry. For flow cytometry, the cell suspension is put under pressure such that the cells flow past a laser in a stream of single cells. The laser will excite the fluorescently labeled antibodies bound to the lymphocytes. A light detector counts the labeled cell as the fluorescent tag emits light and determines the cell size based on its light scatter characteristics. These evaluations are valuable for the assessment of patients with immune deficiency states such as AIDS or leukemias, and for patients who have received hematopoietic stem cell or organ transplants. For example, the number of CD4+ cells in HIV-positive patients correlates with the risk of opportunistic infection and delineates the time to initiate antiviral therapy. Some of the more common CD antigens and their respective cellular distribution are listed in Table e106-8.[50] Flow cytometry can be used for leukocyte phenotyping, tumor cell phenotyping, and some types of DNA analysis.

TABLE e106-8

Cluster of Differentiation (CD) Guide: Characterization of Human Leukocyte Antigens

CD	Predominant Cellular Distribution
CD3	All T-lymphocytes
CD4	Helper T-lymphocytes, either TH1 or TH2
CD5	T-lymphocytes, B-lymphocyte subset
CD8	Cytotoxic/suppressor T-lymphocytes
CD14	Monocytes, neutrophils
CD20	B-lymphocytes
CD25	Activated T-lymphocytes, B-lymphocytes, interleukin-2 receptor α-chain (Tac)
CD33	Committed myeloid progenitor cells
CD34	Hematopoietic progenitor cells that include the stem cell
CD56	Natural killer cells
CD83	Dendritic cells

Innate and Adaptive Immunity: Functional Evaluation

Several disease states are characterized by an adequate number of cells but the cells are nonfunctional or they do not produce cytokines to communicate effectively. Although no single test can predict the function of the immune system, available tests can measure the viability of certain cell lines and communication between cells. Historically, the most common in vivo assay of lymphocyte function is the delayed hypersensitivity skin test. This test specifically evaluates the presence of delayed-type hypersensitivity or the presence of memory T-lymphocytes. Specifically, a small amount of antigen, of which the patient is known to have been previously exposed, is administered. Under normal immunologic host conditions, exposure to this amount of antigen in the skin should produce lymphocytic infiltrate into the area within a few hours, followed by additional lymphocyte recruitment and phagocytes (eg, macrophages and neutrophils) translocation. The maximal intensity of the inflammatory reaction occurs by 24 to 72 hours. This reaction is often referred to as type IV hypersensitivity (ie, cell mediated; see Chapter e108). A delayed-type hypersensitivity reaction is a test of cell-mediated immunity used to assess immunocompetency. The most common method to assess delayed-type hypersensitivity is to administer intradermally a panel of recall antigens. Commonly used antigens include *Candida albicans*, mumps, Trichophyton, tetanus toxoid, and purified protein derivative of tuberculin.[51] Measurements in millimeters of induration at the site of injection should be taken 48 to 72 hours after the placement of the antigens. A reaction is considered positive if the diameter of the induration is 2 mm or greater. The degree of sensitivity correlates with the area of induration.[50] Reaction to even a single antigen indicates a functioning cell-mediated immune response. Most immunocompetent individuals will show a positive reaction to at least one of these antigens. Possible reasons for not mounting a response to these antigens include congenital T-lymphocyte deficiency, cancer, HIV, or immunosuppressive drug therapy.[51] No response is sometimes mounted because the individual being tested has not been previously exposed to a particular test antigen, although this is rare.

Global assessment of the in vivo immunologic response is also commonly used in solid organ transplantation during the diagnosis and assessment of acute rejection. For example, pathologists can detect cellular rejection on gross tissue biopsy by counting the number of lymphocytes present in the tissue and correlating their presence with other clinical findings, such as increased serum creatinine in kidney transplant recipients.

In vivo assessment of B-lymphocyte function involves immunizing the patient with a protein (eg, tetanus toxoid) and a polysaccharide (eg, pneumococcal polysaccharide vaccine) antigen to elicit and measure antibody responses after immunization. Two to three weeks after immunization, the patient's serum is tested for antibodies specific for the immunized antigen. This test measures B-lymphocyte responsiveness to the inoculated antigens but is reserved for patients who are suspected to have impaired B-lymphocyte function.[49]

A number of specific in vitro lymphocyte functional assays are used in the research setting and a few assays are performed at specialized clinical laboratories. One of these tests is the lymphocyte proliferation assay. In this assay, lymphocytes are obtained from a patient's peripheral blood and cultured in vitro. The cells are exposed to nonspecific mitogens, such as pokeweed mitogen, phytohemagglutinin, or concanavalin A. Then the cells are incubated in growth media containing tritium-labeled (^{3}H) thymidine, a nucleotide used in the synthesis of DNA. Normally in the presence of the mitogens, lymphocytes will be stimulated to proliferate. Proliferating lymphocytes will incorporate ^{3}H thymidine as they replicate DNA. The level of radioactivity of the cells can be measured on a β-scintillation counter and is proportional to the degree of proliferation. The patient sample needs to be compared to lymphocytes from normal, healthy subjects. Patients with immune deficiencies (eg, AIDS and cancer) have fewer or less-active lymphocytes, as detected by this test.

A modification of the lymphocyte proliferation assay can be used in allogeneic hematopoietic stem cell transplantation to evaluate how closely a donor and host are "matched" to predict a patient's risk for developing graft-versus-host disease. A mixed lymphocyte culture (MLC) can be used to assess the potential of the donor cells to attack the host cells, graft-versus-host disease (see Chapter e163). In this test, donor cells and host cells are incubated in vitro. The host lymphocytes are irradiated prior to the incubation so that they cannot proliferate. In vitro, ^{3}H thymidine is provided to the cells and uptake is measured. The degree of uptake correlates to the level of proliferation of donor lymphocytes. If the cells are well matched, proliferation is minimal. If the cells are mismatched, proliferation will be noted with the level of proliferation predictive of the risk and severity of graft-versus-host disease. With the introduction of DNA-based, "high resolution" molecular typing of HLA antigens, the MLC is rarely used today.[51]

The Cylex Immune Cell Function Assay is an FDA-approved test used to determine the magnitude of suppression of CD4+ cells.[52] Briefly, CD4+ cell activity is measured by quantification of the amount of ATP produced and characterized as high, medium, or low.[53] Initial retrospective experience has been reported in the solid organ transplant population. This assay is one of the first functional assays aimed at assessing individual patient response to immunosuppressive therapy and may allow for tailoring of immunosuppression.

Evaluation of immune cell activity such as factor forkhead box P3 (FOXP3) Treg-cell activity has been used to evaluate the incidence and severity of acute rejection based on elevated FOXP3 mRNA expression in urine and tissue cell samples. Since Tregs control autoimmune reactions, the presence of these cells in an allograft may indicate a level of "tolerance" to the donor tissue. Tolerance is a state in which the body knows that foreign tissue (eg, kidney transplant) exists but does not attack it. Initial studies have evaluated biopsy samples from organ transplant recipients and correlated them with levels of FOXP3. FOXP3 is present only during periods of inflammation, such as rejection, and potentially projects the allograft tissue.[54] In addition to the tests described earlier, several other tests and assays have been devised to evaluate the function of CD8+ T-lymphocytes, NK cells, and monocytes/macrophages. Although these evaluations are not commonly performed, they may be helpful in some specific diseases and may eventually be the way in which we monitor and detect immunologic events in the future. A thorough discussion of these tests is available.[55]

Immunoglobulins

The measurement of immunoglobulins is a direct measure of B-cell function. The most common evaluation of immunoglobulins is the measurement of individual isotypes by immunoturbidity or immunonephelometry techniques. Although serum protein electrophoresis (SPEP) provides an estimate of the total immunoglobulin concentration, this technique is primarily used to investigate plasma cell dyscrasias and quantitate specific monoclonal protein peaks (eg, multiple myeloma and Waldenstrom macroglobulinemia). Depending on the specific SPEP technique, five or six separate zones are detected by this method: albumin, α1-globulin, α2-globulin, β-globulin (or β1 and β2 by some techniques), and γ-globulin.

⑤ The γ-globulin fraction contains the five isotypes of immunoglobulin (IgG, IgA, IgM, IgE, and IgD). A normal total immunoglobulin or γ-globulin concentration ranges from 0.8 to 1.6 g/dL (8-16 g/L). Total immunoglobulin or γ-globulin concentrations cannot be used to measure antigen-specific antibodies or specific isotypes, although they can be measured with other laboratory tests. In a patient suspected of having humoral immune deficiency or B-lymphocyte failure (primary and secondary hypogammaglobulinemia), specific immunoglobulin isotypes in the plasma should be measured.

There are many indications for the measurement of antigen-specific antibodies. Some common indications are listed in Table e106-9. More contemporary methods to perform these measurements include enzyme-linked immunosorbent assay (ELISA) and a variety of other immunoassay techniques. The most common reason to measure antigen-specific antibody is to determine whether or not a patient has been exposed to an infectious agent. Generally, IgM antibodies directed against the pathogen indicate an active or recent infection while IgG antibodies directed against the pathogen indicate prior exposure. This observation correlates with our understanding of B-lymphocyte responses in which plasma cells produce IgM initially in response to an infection, but later switches to IgG. Therefore, IgM antibodies will be present during an active infection and shortly after recovery from the infection. IgG concentrations will increase at the end of the primary exposure but predominate after a second exposure. IgG predominates after a second exposure because memory B-lymphocytes predominately secrete IgG in the serum. Other uses of antigen-specific antibody include determining if a patient has had exposure and is likely to be protected from infection (eg, hepatitis A virus) or to determine adequate response to vaccination (eg, hepatitis B vaccine). Measurement of antihuman IgG antibodies is used before and after solid organ transplant to detect and potentially predict allograft compatibility and treat antibody-mediated rejection.

TABLE e106-9

Potential Indications for Measurement of Antigen-Specific Antibody

Environmental or drug allergy
Exposure to or infection with bacteria
Streptococci (ASO titer)
Staphylococcus aureus (teichoic acid antibody)
Neisseria gonorrhoeae
Legionella pneumophila
Exposure to or infection with viruses
Human immunodeficiency virus
Cytomegalovirus
Epstein–Barr virus
Hepatitis A, B, or C
Rubella
Exposure to or infection with other pathogens
Syphilis
Lyme disease
Typhoid
Chlamydia
Immune disorders
Rheumatoid factor antibody, rheumatoid arthritis
Antinuclear antibodies, systemic lupus erythematosus
Platelet-associated immunoglobulin G, idiopathic thrombocytopenic purpura
Blood typing and crossmatching
Transplantation
Human leukocyte antigen (HLA) antibodies

Antigen-specific IgE is not commonly measured in patients with allergies. Because the presence of antigen-specific IgE is related to clinical allergy, measurement of these antibodies can help to diagnose allergies and determine offending substances, but the circulating levels are so low they do not normally lead to interpretable results. Contemporary laboratories use enzyme-labeled anti-IgE antibody as a conjugate, with the use of an appropriate substrate for chemiluminescent, fluorescent, or colorimetric detection. The basic technique involves adding the antigen of interest, which is typically bound to beads or disks, to the patient's serum. After incubation and several washings, an enzyme-labeled antibody to IgE is added to bind to any IgE antibody bound to the antigen. After further washings, the enzyme-antibody conjugate bound to IgE, which is bound to the antigen on the bead or disk, is measured by an appropriate substrate that generates the measurement signal and is quantified.

Antigen skin testing is the preferred method to determine the presence of allergen-specific IgE. When produced, IgE binds to high-affinity IgE Fc receptors on basophils or mast cells. Contact of an allergen with the specific IgE on the basophil or mast cell surface causes activation of these cells and the release of inflammatory mediators (eg, histamine). When this occurs systemically, it can cause anaphylaxis. When it occurs in a confined area, such as the skin, erythema and induration are observed within a few minutes of allergen injection. This is the method used to detect penicillin allergy and environmental or food allergies. A positive skin reaction (≥ 5 mm of induration) within 15 to 20 minutes indicates the presence of allergen-specific IgE.

The four subclasses of IgG: IgG1, IgG2, IgG3, and IgG4 make up 65%, 20%, 10%, and 5% of total plasma IgG, respectively. Concentrations of the subclasses are often measured in patients with suspected primary and secondary hypogammaglobulinemia. IgG2 and IgG4 deficiencies are associated with chronic infections. IgG4 deficiencies are also associated with autoimmune disorders.

Complement System

The complement system consists of over 30 different proteins that lyse and opsonize invading pathogens and serve as chemotactic factors. Numbers following the letter C (eg, C1 and C2) refer to the various proteins of the complement system. Assessment of the complement system is important in patients suspected of having humoral immune deficiencies (ie, recurrent infections).[50] A test for the global assessment of the complement system is the CH50, the total hemolytic complement test. This test is based on the premise that complement is needed for a rabbit anti-sheep antibody to lyse sheep red blood cells. The source of the complement is the patient's serum. The normal range varies because each laboratory standardizes the test, but a standard curve is developed by adding titrated amounts of sera and measuring the amount of hemolysis. Hemolysis is determined with a spectrophotometer based on the amount of hemoglobin released. The patient's serum is then tested, and the amount of serum needed to lyse 50% of the red blood cells is reported as the CH50. Many laboratories assess total complement activity with semiquantitative enzyme immunoassay methods based on enzyme-conjugated monoclonal antibodies that bind to newly expressed antigens of the terminal complement proteins or methodology based on lysis of antibody sensitized dinitrophenyl-labeled liposomes with trapped glucose-6-dehydrogenase. These tests do not measure the function of any specific complement component but are used as a screening test for any complement system defects. If a defect is found, individual complement proteins can then be evaluated by either functional or immunochemical methods.

Several disease states can alter complement concentrations. Low complement concentrations are frequently found during states of acute inflammation (eg, systemic lupus erythematosus, rheumatoid arthritis, collagen vascular disorders, poststreptococcal glomerulonephritis, and subacute bacterial endocarditis). These states of low complement concentrations are generally related to high rates of complement utilization or consumption that cannot be compensated for by increased complement synthesis.[22]

Since the liver is the primary source of several components of the complement system (ie, C2, C3, C4, factors B and D), a global decrease in complement factors can occur in severe liver failure. Inherited complement deficiencies have been described in patients with systemic lupus erythematosus, autoimmune diseases, recurrent gonococcal and meningococcal infections, membranoproliferative glomerulonephritis, and hereditary angioedema.[22]

The complement system has been used to diagnose and treat solid organ rejection. Antibody-mediated or humoral rejection is evaluated by measuring the amount of donor MHC-specific antibody present in the recipient's serum. The presence of donor-specific antibodies is correlated with evidence of antibody-mediated rejection on tissue samples. This is characterized by the presence of complement split products, namely C4d, which is present after complement-dependent antibody-mediated rejection. C4d covalently binds to the allograft tissue and can be stained for biopsy samples. Unfortunately, unless biopsy findings can be correlated with a clinical finding consistent with rejection, the presence of C4d and its prognosis on long-term allograft function are unknown.

Cytokines

Disease states involving the loss or upregulation of cytokines are sometimes overlooked as diseases of the immune system. However, as we have just discussed, cytokines are essential components of both the innate and adaptive immune systems and provide the communication linking them together. Multiple cytokines with overlapping and redundant functions have been identified. Methods to detect and measure cytokines in biological samples have been developed. For nearly all the identified cytokines, commercial kits are available to measure endogenous and exogenously administered cytokines. The most common and preferable methods to measure cytokines are ELISAs (enzyme-linked immunosorbent assay) and RIAs (radioimmunoassay). ELISAs, RIAs, or enzyme immunoassays are easy to perform and can identify and quantify the presence of cytokines, but they do not intrinsically measure biologic activity (see Fig. e106-7). Bioassays measure biologic activity, but are cumbersome and extremely variable. ELISA is only able to measure how much cytokine is produced by the cells in the culture. An ELISPOT is an enzyme-linked assay for detecting and enumerating cytokine-producing leukocytes.[56] In contrast to conventional ELISA, ELISPOT allows the user to detect absolute numbers and frequencies of cytokine-secreting leukocytes.

FIGURE e106-7

Enzyme-linked immunosorbent assay (ELISA). ELISA is a commonly used method for measuring concentrations of a wide variety of substances. To measure the concentration of antibodies to a particular antigen, the antigen is coated onto a solid phase, such as a microtiter plate or beads. If the purpose of the assay is to measure the concentration of antigen in solution, an antibody to the antigen is coated on the solid phase. The biologic fluid, often sera, is added to the wells. An enzyme-labeled antihuman antibody is added next. Finally, the chromogenic substrate for the enzyme is added. The intensity of the color as measured spectrophotometrically is proportional to the concentration of the antibody in the biologic fluid.

The clinical relevance of endogenous cytokine concentrations is not clear. Not only is the immune system affected by cytokines, such as IL-1, IL-6, and TNF-α, but other systems (skeletal, endocrine, and CNS) are also affected. Therefore, measurement of cytokine concentrations may be important to evaluate other systems in addition to the immune system.

Administration of recombinant cytokines in clinical practice may change not only the concentration of that particular cytokine but also the resultant concentration of other cytokines. For example, systemic administration of GM-CSF to patients not only increases concentrations of GM-CSF but also of TNF-α, IL-6, IL-8, macrophage CSF, and EPO.[57,58] Secondary endogenous cytokine release should be taken into account when considering the therapeutic effects of these agents and when monitoring cytokine concentrations.

In the future, blood and tissue cytokine concentrations may be measured. For example, while many centers measure blood cyclosporine or tacrolimus concentrations to ensure adequate immunosuppression, it may be advantageous to monitor IL-2 concentrations because one of the primary actions of calcineurin inhibitors is to inhibit IL-2 production. Furthermore, perhaps it would be beneficial to measure tissue IL-2 concentrations in the transplanted organ to get a better estimate of the extent of immunosuppression.

Soluble Receptors and Receptor Antagonists

The inflammatory response is highly regulated. The activity of cytokines, their receptors, and their antagonists are in a delicate balance. Although cytokine receptors are usually found on the target cell, soluble cytokine receptors can modulate cytokine activity in at least two ways: (a) acting as anti-inflammatory agents by binding cytokines with high affinity, but without biological activity; and (b) augmenting cytokine activity by prolonging the cytokines plasma half-life and even maintaining agonist activity on cells that do not inherently respond to the cytokine.[59,60] Finally, antagonists to cytokine receptors have been identified.

TNF-α plays a central role in the inflammatory response by increasing the expression of adhesion molecules in the tissues and by stimulating the production of proinflammatory cytokines (eg, IL-2 and IL-8), prostaglandins, and nitric oxide. Soluble tumor necrosis factor receptors (sTNFRs) act primarily as inhibitors of TNF by preventing TNF from binding to the membrane-bound TNFRs, or by causing the cells to shed the receptor from the surface of the cell so that it can no longer serve as a signaling molecule.[61] Both monoclonal antibodies against TNF (eg, infliximab and adalimumab) and sTNFRs (eg, etanercept) have been shown to modulate the activity of TNF and are used clinically for the treatment of autoimmune diseases.

The best-characterized receptor-binding antagonist is the interleukin-1 receptor antagonist (IL-1RA). IL-1RA blocks the binding of IL-1 to its receptor by competing for the same binding site, but IL-1RA does not possess agonist activity.[62] A recombinant IL-1RA, anakinra, is used clinically for the treatment of severe rheumatoid arthritis.[63]

Our developing understanding of soluble receptors and receptor antagonists allows us to better mimic natural mechanisms for minimizing the toxicity of exogenously administered cytokines (eg, IL-1, IL-2, and TNF-α) and to immunomodulate various diseases (eg, solid-organ transplant rejection, collagen vascular disorders, inflammatory bowel disorders, autoimmune dermatologic conditions, and sepsis).

MODULATION OF THE IMMUNE RESPONSE

⑥ Modulation of the immune response through the administration of pharmacological agents or with blood product components comes with both risks and benefits. One example is the administration of recombinant activated protein C (drotrecogin alfa) to patients in septic shock. Administration of recombinant activated protein C reduced levels of IL-6, a potent proinflammatory cytokine that is thought to contribute to many of the clinical manifestations of septic shock. Unfortunately, protein C also possesses anticoagulant and fibrinolytic properties, leading to a significantly increased risk of bleeding. As a result, no survival benefit was observed when drotrecogin alfa was given to patients in septic shock. This ultimately led to the withdrawal of drotrecogin alfa from the market.[64] Another example of drugs with both risks and benefits is TNF inhibitors. While TNF inhibitors suppress the immune system to halt the damage of autoimmune disorders and alleviate symptoms, they also increase the risk of opportunistic viral infections. Many of our newer biological agents directed at immune pathways are derived from animals and are subsequently humanized with various genetic engineering techniques to increase their biological effectiveness and decrease their antigenicity. Despite these efforts, these agents can serve as antigens and elicit an immune response, which may have a variety of consequences such as decreased efficacy over time. For example, an agent commonly used in solid organ transplantation is rabbit antithymocyte globulin (rATG), a polyclonal antibody derived from rabbits that have been immunized against human lymphocytes. rATG is sometimes given to prevent or treat graft rejection in patients undergoing solid organ transplantation. Patients with previous exposure to rATG can develop antibodies against the drug because the rabbit antibodies can be antigenic in humans. This can result in decreased effectiveness of rATG, because the rabbit antibodies are neutralized by human antirabbit antibodies (HARAs). Once rATG is bound by HARAs, rATG is no longer able to bind to its target (ie, human lymphocytes). Another potential consequence of HARAs is the deposition of the HARA/rATG complex in the kidneys and joints, producing high fevers and renal failure. Based on these examples, one can understand why manipulation of the immune system must be carefully assessed and appropriate patient instruction given.

Immunosuppression

Immunosuppression was first developed and used to allow transplantation of foreign tissues or to treat malignancies of the immune system. These medications are usually expensive and associated with potentially serious adverse drug reactions. Immunosuppressants block critical steps of the immune response, and patients must be counseled on their risk of infection and the plan to monitor the effectiveness of the immunosuppressant. As we learn more about the function of the immune system, various immunosuppressive medications targeting a growing number of immunoregulatory pathways are being used to treat autoimmune diseases, including irritable bowel and Crohn's disease, dermatologic conditions such as psoriasis, multiple sclerosis, as well as rheumatoid arthritis and psoriatic arthritis. Current pharmacologic targets that result in immunosuppression include calcineurin (cyclosporine, voclosporin), FKBP12/calcineurin (tacrolimus, sirolimus, everolimus), inosine monophosphate dehydrogenase (IMDPH) (mycophenolate), TNF-α (adalimumab, certolizumab, etanercept, golimumab, infliximab), IL-1 (anakinra), IL-2 (basiliximab), IL-6 (sarilumab, tocilizumab, satralizumab), IL-12 (ustekinumab), IL-13 (tralokinumab), IL-17 (secukinumab, brodalumab, ixekizumab), IL-23 (tildrakizumab, ustekinumab, risankizumab, guselkumab), the Janus Associated Kinase/Signal Transducer and Activator of Transcription (JAK/STAT) pathway (baricitinib, tofacitinib, upadacitinib), CD80/CD86 (abatacept, belatacept), and the cellular adhesion pathways that lymophcytes use to navigate into various tissues (natalizumab, vedolizumab). Sphingosine 1 plays an important role in lymphocytes' ability to exit lymph nodes, and several sphingosine 1-phosphate receptor modulators reduce immune-mediated damage in multiple sclerosis (ozaminod, ponesimod, fingolimod, siponimod). In 2021, several drugs targeting various elements of the complement system were granted approval for various autoimmune disorders: complement C3 (pegcetacoplan) and complement C5a receptor (avacopan). Other new targets for immunosuppressive drugs that have emerged include Rho-associated coiled-coil-containing kinase 2 (ROCK2) inhibitors (belumosudil), type-1 interferon receptor antagonists (anifrolumab), and neonatal Fc receptor antagonists (efgartigimod). As noted above, most, if not all of these medications increase the risk of various types of infections. Several also increase the risk of certain types of cancers derived from immune cells, as well as unusual immune-related adverse events. It is critically important for clinicians to weigh the risks and benefits of these medications. Several key concepts and questions can be used to help clinicians discern the potential benefits and harms of administering any immunosuppressant. These include: (a) what is its mechanism of action, (b) what arm of the immune system does it effect, (c) when is its onset of action, (d) how was this compound derived and does it have the potential to stimulate antibody production if the patient is reexposed, (e) is this compound's effect dose- or duration-related, (f) what type of infection is the patient at risk for and is infection prophylaxis required, and (g) how do I monitor the biological effect of this compound?

Immunopotentiation

Immunopotentiators can be used to restore normal immune system function or to activate the immune system. The best example of immunopotentiation of the immune system is the practice of immunizations. Active immunization with a vaccine or toxoid induces the host's immune system to confer protection against a pathogen (eg, hepatitis A, hepatitis B, and diphtheria toxoid). This process requires the uptake of the immunogenic epitope by APCs followed by presentation to CD4+ T-lymphocytes and the subsequent development of either a cellular or humoral immune response. Another example of immunopotentiation is the administration of IL-2 to patients with malignant melanoma. As previously discussed, IL-2 is a potent activator of T-lymphocyte and NK cell activity, which can be sufficient to break immune tolerance and result in immune-mediated tumor destruction.[65]

In contrast to active immunization, passive immunity involves the administration of human immunoglobulin to provide short-term protection to individuals who will be or have been exposed to a pathogen. IV immunoglobulin (IVIG) consists of more than 90% polyclonal IgG prepared from donated plasma. In patients with primary or secondary hypogammaglobulinemia, IVIG restores circulating IgG concentrations and decreases the risk of infections. In addition to restoring IgG concentrations, IVIG can potentially modulate the immune response. For example, in immune thrombocytopenic purpura, an autoantibody directed against the platelets leads to the destruction of the platelets by antibody-dependent cellular cytotoxicity. IVIG saturates the Fc receptors on phagocytic cells, thereby preventing the engulfment of autoantibody-opsonized platelets. IVIG can also contain anti-idiotype antibodies to modulate an immune response. Anti-idiotype antibodies are directed against the idiotype or hypervariable region of a native antibody. After administration of IVIG, the anti-idiotypes bind to the hypervariable region of the autoantibody and prevent the autoantibody from opsonizing circulating platelets. In addition, the anti-idiotypes directed against the autoantibody can bind to the surface immunoglobulin on the B-lymphocyte producing the autoantibody that leads to the destruction of the B-lymphocyte.[66]

Through our increased understanding of critical steps in T-lymphocyte responses, several monoclonal antibodies that enhance T-lymphocyte activity have been developed to treat cancer. These drugs are classified as immune checkpoint inhibitors. Immune checkpoints are inhibitory pathways that decrease T-lymphocyte activity. Cancer cells can use immune checkpoints to evade recognition by the immune system. When these inhibitory checkpoint pathways are blocked with monoclonal antibodies, T-lymphocyte activity is increased. The first checkpoint inhibitor to be approved was ipilimumab, a humanized monoclonal antibody that binds to CTLA-4 on activated T-lymphocytes. Blockade of CTLA-4 prevents the inhibition of T-lymphocytes mediated by CTLA-4 signaling and thus releases them to attack their target. Single-agent ipilimumab improves overall survival in patients with unresectable or metastatic melanoma.[67] Four additional agents, pembrolizumab, nivolumab, cemiplimab, and dostarlimab bind to PD-1 on activated T-lymphocytes, preventing PD-L1 or PD-L2 expressed on tumor cells from inhibiting activated T-lymphocytes. In addition to targeting PD-1, it is also possible to target PD-L1, achieving a similar effect. Three drugs, atezolizumab, avelumab, and durvalumab all target PD-L1, and prevent the ligand from binding to the PD-1 receptor on T-lymphocytes. Targeting two immune checkpoint pathways, CTLA-4 and PD-1, with the combination of nivolumab and ipilimumab has even greater antitumor activity than either agent alone in patients with advanced melanoma.[68–70] It is important to note that the inhibition of these immune checkpoint pathways can result in increased activity directed at self-antigens. This phenomenon is, unfortunately, fairly common in patients receiving immune checkpoint inhibitor-based therapies, and is known as an immune-mediated adverse event. These immune-mediated adverse events most commonly manifest as colitis, hepatitis, dermatitis, pneumonitis, or endocrinopathies, although experience has shown that virtually any tissue type or organ system can be affected.[71–77] It is also important to note that the combination of ipilimumab and nivolumab results in a higher incidence and severity of immune-mediated adverse events.[67–70] Despite these toxicities, immune checkpoint inhibition is one of the fastest growing areas of cancer treatment and research. In fact, since ipilimumab was first approved by the FDA in 2011, immune checkpoint inhibitors have been approved by the FDA for the treatment of at least 15 different cancers. These cancers include colorectal cancer (for patients with microsatellite instability-high or mismatch repair deficient tumors), cervical cancer, cutaneous squamous cell carcinoma, gastric cancer, hepatocellular carcinoma, Hodgkin lymphoma, melanoma, Merkel cell carcinoma, nonsmall cell lung cancer, primary mediastinal large B-cell lymphoma, renal cell carcinoma, small cell lung cancer, squamous cell cancer of the head and neck, urothelial carcinoma, and any solid tumor that expresses a high level of microsatellite instability.

Sipuleucel-T immunotherapy shows significant activity in castration-resistant prostate cancer. Sipuleucel-T takes advantage of our increased knowledge of APCs. Sipuleucel-T involves isolation of APCs from a patient by leukapheresis followed by in vitro activation of the APCs with a recombinant fusion protein, PA2024, which contains GM-CSF to activate the APCs and a tumor antigen, prostatic acid phosphatase (PAP), common to prostate cancer. Finally, the activated APCs are reinfused into the patient every 2 weeks. The activated APCs then present PAP to the patient's T-lymphocytes, which then leads to increased numbers of T-lymphocytes attacking the prostate cancer (Fig. e106-8).[78]

FIGURE e106-8

Chimeric Antigen Receptors are comprised of an extracellular domain consisting of the single chain variable fragment (ScFv) portion of an antibody, a transmembrane domain, and an intracellular domain, which usually contains one or more costimulatory domains. The number and type of costimulatory domains may affect the cytotoxicity, cell growth, and survival characteristics of the T-cell.

Adoptive cell transfer (ACT) is an active area of cancer research that shows great promise. ACT uses a patient's own T-lymphocytes, derived either from a surgically resected tumor specimen or from peripheral blood and genetically engineered to express antitumor TCRs, to treat cancer.[79] In one study of patients with advanced melanoma, 40% of patients achieved a complete response that lasted at least 2.5 years.[80] As our understanding of the immune system has expanded, more advanced genetic engineering techniques have allowed a wider variety of cancers to be targeted through ACT. One particular type of ACT involves creating a highly modified version of a TCR, known as a Chimeric Antigen Receptor (CAR), in which the extracellular domain of the TCR is replaced with a portion of an antibody, while the intracellular signaling domain is either left alone or modified to include various costimulation domains (see Fig. e106-8). In patients with chemotherapy-refractory B-cell malignancies, CAR T-cell targeting CD19 resulted in a 53% complete response rate, with some responses lasting almost 2 years.[81] This early research led to the development of two FDA- approved CAR T-cell therapies, both of which target CD19. The first FDA-approved CD19 CAR T-cell therapy was tisagenlecleucel, which is approved to treat refractory or relapsed B-cell precursor acute lymphoblastic leukemia, and B-cell lymphomas.[82,83] The second FDA-approved CD19 CAR T-cell therapy was axicabtagene ciloleucel.[84] Five CAR T-cell therapies have been FDA-approved for hematological malignancies. There is tremendous interest in applying this approach to other cancers, and beyond. For example, some experts believe that CAR T-cell technology can be used to treat infectious diseases that are historically difficult to treat such as drug-resistant bacterial infections or HIV.[85,86] As we continue to expand our knowledge of the immune system and its complex interactions, we will develop new therapeutic approaches to modulate immune responses in the treatment of human diseases.

CONCLUSION

As our understanding of the immune system and its function has continued to expand, so too has our ability to specifically target and modulate the immune response for therapeutic purposes. New technologies have allowed us to suppress specific immune functions or to upregulate immune activity either broadly or specifically by targeting specific subsets of the immune system. These new therapeutic options have wide-ranging implications, from the treatment of various autoimmune disorders to new therapeutic options for cancer and possibly for infectious diseases. Equally important is an understanding of the implications of suppressing or upregulating immune function so that immune-related adverse events or opportunistic infections can quickly be identified and treated when they occur. A solid understanding of the structure and function of the immune system will become increasingly important for clinicians as we continue to harness, modulate, and assess the immune system to treat disease.

ABBREVIATIONS

APC	antigen-presenting cell
CAR	chimeric antigen receptor
CD	clusters of differentiation
CD4	T-helper cells
CD8	T-cytotoxic cells
CRP	C-reactive protein
CSF	colony-stimulating factor
DC	dendritic cell
ELISA	enzyme-linked immunosorbent assay
EPO	erythropoietin
FasL	Fas ligand
Fc	fragment crystallizable
FOXP3	factor forkhead box P3
GM-CSF	granulocyte-macrophage colony-stimulating factor
HLA	human leukocyte antigen
IgG	immunoglobulin G
IL	interleukin
IL-1RA	interleukin-1 receptor antagonist
IVIG	intravenous immunoglobulin
MALT	mucosa-associated lymphoid tissue
MHC	major histocompatibility complex
MIP	macrophage inflammatory protein
NK	natural killer
PAMPs	pathogen-associated molecular patterns

PD1	programmed cell death 1
PRRs	pattern recognition receptors
RIA	radioimmunoassay
sIg	surface immunoglobulin
SPEP	serum protein electrophoresis
TCR	T-cell receptor
TH1	T-helper type 1
TH2	T-helper type 2
TH17	T-helper 17 cells
Tregs	T-regulatory cells
TNF-α	tumor necrosis factor-α
WBC	white blood cell

SELF-ASSESSMENT QUESTIONS

1. Which of the following receptors does not inhibit T-cell activity?

   A. PD-1

B. CD28

C. CTLA-4

D. Fas

2. Which of the following is a part of the adaptive immune system?

A. Macrophage

B. Eosinophil

C. B-cell

D. Neutrophil

3. Which antibody type is usually produced when the immune system first encounters a pathogen?

A. IgA

B. IgD

C. IgG

D. IgM

4. Activation of the complement system can result in all of the following, except:

A. The stimulation of plasma cells to secrete antibodies

B. Opsonization of foreign pathogens

C. Lysis of microorganisms

D. Stimulation of chemotaxis of phagocytes

5. Which of the following treatments depends on passive immunity?

A. Tetanus vaccine

B. Cyclosporine to prevent transplant rejection

C. Antivenin to treat a rattlesnake bite

D. Nivolumab to treat metastatic melanoma

6. Which of the following is not an example of physical or chemical defense against pathogens?

A. Stomach acid

B. Lysozymes in tears

C. Cilia on epithelial cells in the lung

D. Langerhans cells in the skin

7. Which of the following is a pattern recognition receptor?

A. Toll-like receptor on macrophages

B. Surface immunoglobulin on B-cells

C. T-cell receptor on T-cells

D. Killer-activating receptors on NK cells

8. Which of the following is an example of a humoral immune response?

A. A neutrophil phagocytosing a pathogen

B. An IgG molecule binding an antigen on a viral pathogen

C. An NK cell destroying a virally infected cell

D. A CD4+ T-cell secreting IL-2 to activate CD8+ T-cells

9. T-cells mature in which of the following organs?

A. Bone Marrow

B. Lymph Nodes

C. Spleen

D. Thymus

10. Which of the following medications stimulates immune activity?

A. Pembrolizumab

B. Infliximab

C. Adalimumab

D. Vedolizumab

11. Which of the following is a CAR T-Cell–based treatment?

A. Sipuleucel-T

B. Axicabtagene ciloleucel

C. Talimogene laherparepvec

D. Trastuzumab emtansine

12. All of the following have been shown to result in decreased concentrations of complement except:

A. Liver failure

B. Systemic lupus erythematosus

C. Hereditary angioedema

D. Type 2 diabetes

13. Which of the following is the most common immunoglobulin found in human serum?

A. IgA

B. IgE

C. IgG

D. IgM

14. Which of the following cell markers is present on all T-cells?

A. CD3

B. CD4

C. CD8

D. CD25

15. Which of the following is a mechanism used by cytotoxic T-cells to destroy their targets?

A. Phagocytosis

B. Opsonization

C. Histamine release

D. Perforin release

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** PD-1, CTLA-4, and Fas receptors send inhibitory signals to T-cells once they bind to their ligands. CD28 binds to CD80 or CD86 and is part of the signaling pathway that results in T-cell activation.

2. **C.** Macrophages, eosinophils, and neutrophils are components of the innate immune system. Since B-cells are able to recognize new antigens and develop into memory cells that allow for a more rapid and potent immune response upon additional exposure to an antigen, they are classified as a component of the adaptive immune system.

3. **D.** Upon exposure to a given antigen, plasma cells secret IgM initially. Over time, plasma cells eventually switch over to the secretion of IgG.

4. **A.** The complement system does not signal plasma cells to secrete antibodies. The complement system can opsonize foreign pathogens, preventing the pathogen from interacting with or infecting cells or structures in the body. Additionally, opsonization may signal granulocytes, such as neutrophils to phagocytose and destroy the pathogen. Additionally, the binding of complement has been shown to result in the lysis of certain microorganisms and cells. Finally, breakdown products of complement (C3a and C5a) can serve as chemoattractants which attract neutrophils to infected tissues.

5. **C.** When we administer antivenin, we are administering exogenously produced antibodies to a patient to neutralize a venom with which the patient has been envenomated. This is an example of passive immunity because the patient is not producing the antibodies themself. Following a tetanus vaccine, the individual's B-cells recognize the antigens in the tetanus vaccine and develop a memory against these antigens, an example of active immunity. Cyclosporine is a potent inhibitor of T-cell activation and it is given to inhibit an active immune response (eg, to prevent transplant rejection or graft-versus-host disease). Finally, nivolumab, a PD-1 inhibitor, prevents the inhibition of T-cells. When we administer nivolumab, we are increasing the activity of the immune system by stimulating an active immune response against cancer cells.

6. **D.** Stomach acid, lysozyme in tears, and cilia on epithelial cells in the lungs are examples of physical or chemical defenses against invading pathogens. Langerhans cells are a type of dendritic cell found in the skin. Dendritic cells serve as antigen-presenting cells, which play an important role in the activation of T-cells and B-cells.

7. **A.** Toll-like receptors are pattern-recognition receptors that bind to highly conserved structures present on a large number of different microorganisms. When a pattern recognition receptor (which is expressed on phagocytes) binds to its target, the cell expressing the target is immediately phagocytosed. In contrast, surface immunoglobulins, T-cell receptors, and killer-activating receptors recognize specific targets and require multiple interactions with the target and other cells to initiate an immune response.

8. **B.** Examples of cellular immunity include neutrophils phagocytizing a pathogen, NK cells destroying a virally infected cell, and CD4+ T-cells secreting IL-2 to activate CD8+ T-cells. IgG binding an antigen on a viral pathogen is an example of humoral immunity, which generally refers to antibody-based responses.

9. **D.** While all of the options listed represent the major tissues and organs of the immune system, the correct answer is that T-cells mature in the thymus. In fact, T-cells are named T-cells because they mature in the thymus.

10. **A.** Pembrolizumab stimulates immune activity by blocking T-cell inhibition. Infliximab and adalimumab are both monoclonal antibodies that bind to TNF-α, preventing it from binding to TNF receptors. By inhibiting the activity of TNF-α, a pro-inflammatory cytokine, infliximab, and adalimumab decrease immune activity. Vedolizumab is a monoclonal antibody that binds to a specific type of integrin, a molecule that T-cells use to migrate from the bloodstream into inflamed tissues. By preventing T-cells from being able to contribute to an ongoing inflammatory response, the drug decreases immune activity.

11. **B.** Axicabtagene ciloleucel is a CAR T-cell that targets the CD19 receptor on B-cells and is used to treat B-cell malignancies. Sipuleucel-T is a cell-based therapy; APCs are collected from the patient and are exogenously primed with an antigen found on prostate cancer before being reinfused into the patient. Talimogene laherparpvec is a genetically modified herpes simplex virus that is injected directly into melanoma tumors and increases immune response at the site of injection. Trastuzumab emtancine is an antibody-drug conjugate that targets the HER-2 molecule commonly overexpressed on different cancers and delivers a cytotoxic microtubule inhibitor (the emtansine molecule) to the cell.

12. **D.** Decreased complement levels are associated with liver failure, systemic lupus erythematosus, and hereditary angioedema. Type-2 diabetes has not been associated with decreased complement levels.

13. **C.** IgG comprises about 80% of serum immunoglobulins, while IgA makes up about 15%, IgM represents about 5%, IgD is about 0.2%, and only trace amounts of IgE are detected.

14. **A.** CD3 is expressed on all T-cells. CD4 is expressed on a subset of T-cells called Helper T-cells. CD8 is expressed on a subset of T-cells known as cytotoxic T-cells. Finally, CD25 is expressed on activated T-cells and is not present on inactivated T-cells.

15. **D.** T-cells release perforin which forms pores in the membrane of the target cell. These pores allow granzymes, which are also released by the T-cell to enter the target cell and initiate apoptosis in the target cell. T-cells do not phagocytize or opsonize their targets. T-cells also do not produce or release histamine.

Chapter e108: Drug Allergy

Mary L. Staicu; Christopher M. Bland; Bruce M. Jones

KEY CONCEPTS

KEY CONCEPTS

① Drug allergy accounts for 6% to 10% of adverse drug reactions to medications. Most of these immune events are mediated by IgE or activated T cells.

② Three theories—the prohapten/hapten concept, the p-i concept, and the altered repertoire model—have been proposed to explain how drugs stimulate an immune response.

③ Anaphylaxis is an acute, life-threatening allergic reaction involving multiple organ systems that generally begins within 1 hour but almost always within 2 hours after exposure to the inciting allergen. Anaphylaxis requires prompt treatment to restore respiratory and cardiovascular functions. Epinephrine is the drug of first choice and should be administered to counteract bronchoconstriction and peripheral vasodilation. Intravenous fluids should be administered aggressively to restore intravascular volume.

④ Factors that influence the likelihood of drug allergy are the drug's chemical composition, whether the drug contains proteins of nonhuman origin, the route of drug administration, and the individual's sensitivity as determined by genetics or environmental factors. For some drugs, the presence of specific human leukocyte antigen alleles is a risk factor for allergic skin reactions.

⑤ Ideally, cephalosporins should be avoided in patients with a history of an immediate penicillin allergy, but the risk of an allergic cross-response to a cephalosporin, even in a person with a positive penicillin skin test result, is low. Similarities in the R1 side chain of the agents should be considered when assessing the risk of β-lactam cross-reactivity.

⑥ Cross-reactivity between sulfonamide antibiotics and nonantibiotics is low. The low cross-reactive rate may be explained by differences in the chemical structures and reactive metabolites of sulfonamide antibiotics and nonantibiotics.

⑦ In susceptible patients, aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) can produce two general types of reactions, urticaria/angioedema and rhinosinusitis/asthma. Most patients with aspirin sensitivity who require aspirin for the prevention of cardiovascular disease can safely undergo and complete a graded challenge or induction of drug tolerance (previously known as desensitization).

⑧ Fewer than 1% of patients receiving nonionic radiocontrast agents experience some type of adverse reaction. Of the variety of reactions reported, about 90% are nonimmediate and mostly urticarial, with severe immediate reactions occurring as infrequently as 0.02%.

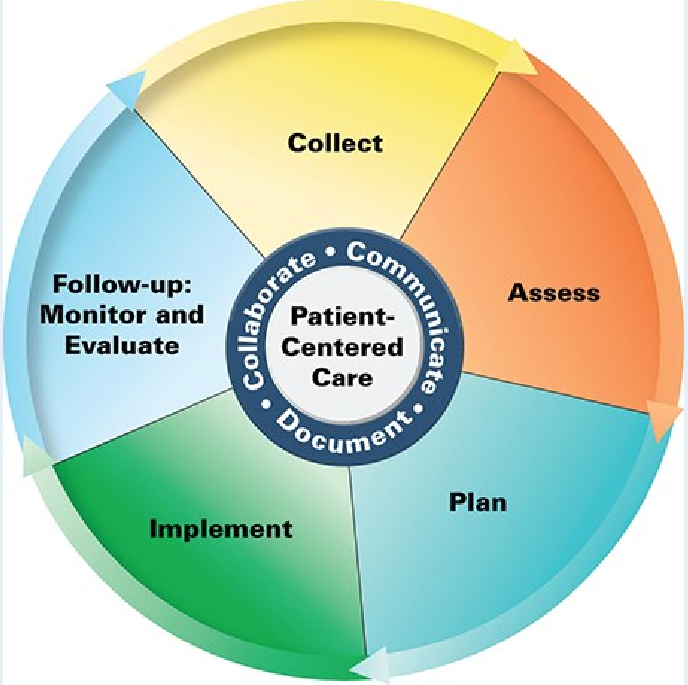
⑨ The basic principles of management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or offending agent when possible; (b) treatment of the adverse clinical signs and symptoms; and (c) substitution, if necessary, of another agent.

⑩ The penicillin skin test is the reference standard for evaluating the risk of immediate hypersensitivity to penicillin. Skin testing can demonstrate the presence of penicillin-specific immunoglobulin E, if present, and predict immediate reactions. Skin testing is not indicated for non-IgE-mediated reactions.

⑪ When an allergenic drug is considered medically necessary and no therapeutic alternative or reliable skin testing method exists, three options are available to the clinician: induction of drug tolerance, graded dose challenge, or rechallenge.

PATIENT CARE PROCESS

Patient Care Process for Drug Allergy



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, sex, pregnancy status)
- Medication history (eg, prescription, OTC, and complementary medications such as herbals)
- Allergy history (eg, medications, foods, environmental exposures with descriptions of each reaction)
- Subjective findings of the allergic reaction (eg, shortness of breath, itching, feeling of flushing, lip-tingling, nausea, lightheadedness)
- Objective data
    - BP, HR, RR
    - Labs (eg, serum electrolytes, serum tryptase, Scr, BUN, LFTs)
    - Observation of the rash, if applicable (eg, type of lesion(s), distribution of lesions, presence or absence of oral or genital ulcerations, presence or absence of bullae)

Assess

- Timing of the reaction relative to the initiation of each of the patient's current medications
- Likelihood of cross-reactivity relative to documented allergy history (eg, previously documented allergy to penicillin in a patient receiving a non-penicillin beta-lactam antibiotic)
- Presence of risk factors (see the "Factors Related to the Risk or Severity of Allergic Drug Reactions" section)
- Coadministration of medications that may increase the risk of an allergic reaction when used in combination (eg, lamotrigine and valproate)
- Severity of the reaction (eg, localized rash vs a systemic reaction involving one or more organs)
- Medications that may interfere with the identification or treatment of the allergic reaction (eg, chronic use of antihistamines when skin testing may be warranted; chronic beta-blocker use in a patient with anaphylaxis)

- Need for drug desensitization or induction of drug tolerance (see Table e108-4)

Plan[*]

- Management of the allergic reaction (see Table e108-2 if patient presents with anaphylaxis)
- Management of the condition for which the allergic medication was indicated (eg, treatment of the underlying infection for which the allergenic antibiotic was indicated)
- Patient education (eg, recognition of likely allergenic medication, risk of cross-reactivity with related agents, use of epinephrine self-injectors, if applicable)
- Referrals to other providers when appropriate (eg, allergist)

Implement[*]

- Provide education to the patient and healthcare providers on an effective management plan
- Drug desensitization or graded challenge protocols, if appropriate
- Drug skin testing, if appropriate

Follow-up: Monitor and Evaluate

- Assess responsiveness to the management plan and revise the plan, if applicable
- Identify most likely causative medication based on responsiveness to drug discontinuation and treatment
- Document allergic reaction and update drug allergy information in medical record
- Reinforce patient education on allergic medication, type of reaction, potential cross-reactive medications, and self-management of reaction (if applicable)

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Listen to the podcast series entitled “The Itch: An SIDP Podcast Miniseries on Penicillin Allergy”: https://sidp.org/podcasts/. These podcasts led by drug allergy experts in the pharmacy field discuss various topics including myth-busting with regards to penicillin allergies, how to successfully implement penicillin skin testing, and finally “lessons learned from the front-line” to help those interested in developing a comprehensive penicillin allergy assessment and skin test program.

INTRODUCTION

① *Drug allergy* is defined by the World Health Organization as an immunologically mediated hypersensitivity reaction to a drug in a sensitized person. This can be further classified as immediate or delayed based on the time of onset in symptoms and the probable immunologic mechanism.[1] The hyper-response of the immune system to the antigenic drug leads to host tissue damage manifesting as an organ-specific or generalized systemic reaction. The International CONsensus (ICON) on Drug Allergy has proposed that the term *drug allergy* be used for drug reactions in which a definite immune mechanism (either antibody- or T-cell-mediated) has been proven. *Drug hypersensitivity reaction (DHR)* is the term that should be used for more heterogeneous reactions that clinically resemble an allergy but may or may not be mediated via an immune response.[2] Examples of drug allergies are anaphylaxis from β-lactam antibiotics, halothane hepatitis, Stevens–Johnson syndrome (SJS) from carbamazepine, heparin-induced thrombocytopenia, allopurinol hypersensitivity syndrome, and serum sickness from phenytoin. Examples of DHRs are isolated urticaria after radiocontrast media, aspirin-induced asthma, opiate-related pruritus, and flushing after vancomycin infusion.[3]

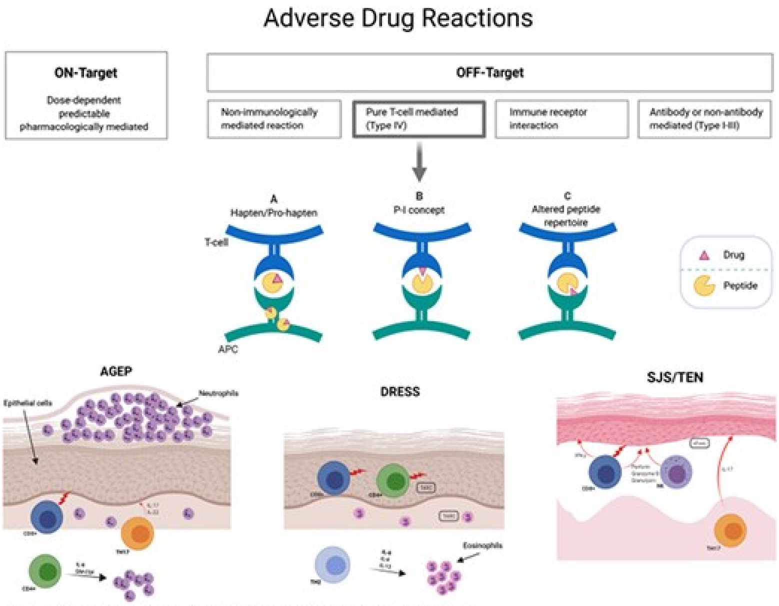
Immune-mediated reactions account for 6% to 10% of all adverse drug reactions and up to 15% when the more heterogenous DHRs are included.[4,5] The true frequency of drug allergies is difficult to determine because many reactions may not be reported, and others may be difficult to distinguish from nonimmune DHRs. Dermatologic reactions represent the most frequently recognized and reported form of drug allergy.

MECHANISMS OF ALLERGIC DRUG REACTIONS

② Drugs can cause allergic reactions by a variety of immunologic mechanisms. Although some reactions are relatively well defined, most are due to mechanisms that are either unknown or poorly understood.[5] Several theories or concepts have been proposed to describe the initiation of an immune response to a drug (see Fig. e108-1).

FIGURE e108-1

T-cell-mediated delayed hypersensitivity mechanistic hypotheses. Three non-mutually exclusive hypotheses have been described to clarify drug-triggered T-cell activation: (**A**) The hapten/prohapten model describes how an antigen (drug) that covalently binds to a self-peptide is intracellularly processed and then presented by MHC to T cells. Alt Text: The illustration shows an antigen presenting cell accepting a protein-bound antigen from a T cell. (**B**) The p-i concept (pharmacological interaction with an immune receptor) is based upon non-covalent binding of antigens to HLA or TCR without immune processing. Alt Text: The illustration shows an antigen bound directly to a T cell which is then being presented to an antigen presenting cell. (**C**) The altered repertoire model indicates that drugs can occupy positions in the peptide-binding groove of the MHC, altering the binding cleft and the specificity of MHC binding. Alt Text: The illustration shows an antigen detected by the antigen presenting cell... HLA, human leukocyte antigens; MHC, major histocompatibility complex; TCR, T-cell receptor. *(Reprinted, with permission, from Copaescu A, Gibson A, Li Y, et al. An updated review of the diagnostic methods in delayed drug hypersensitivity. Front Pharmacol, 2021;11:573–573.)*



Adverse Drug Reactions
ON-Target
Dose-dependent predictable pharmacologically mediated
OFF-Target
Non-immunologically mediated reaction
Pure T-cell mediated (Type IV)

Prohapten/Hapten Concept

This concept is based on the assumption that small-molecular-weight molecules (less than 10 kDa) cannot serve as antigens on their own. Except for polypeptide compounds, most drugs are smaller than 1,000 Da. To become immunogenic, these small compounds must first covalently bind to carrier proteins in plasma or tissue. The combination of the drug bound to a carrier protein is recognized as foreign by antigen presenting cells (APCs) such as macrophages and dendritic cells. The drug's *antigenic determinant*, the drug portion that is immunogenic, is subsequently processed by antigen presenting cells and presented on major histocompatibility complex (MHC) molecules for recognition by T cells, thereby initiating the immune response. Drugs of low molecular weight that combine with a carrier macromolecule for processing by antigen presenting cells are referred to as *haptens* or *incomplete antigens*.[2,7,8] Penicillin G (356 Da) is an example of a drug that binds covalently to serum proteins through amide or disulfide linkages thereby forming a complete antigen. For some drugs, such as sulfonamides, the parent compound must be converted to a metabolite before it can combine with the macromolecule. Drugs that are chemically inert and rely on conversion to a metabolite with an antigenic determinant are referred to as *prohaptens*.[2,7,8] Some macromolecular drugs such as insulin are *complete antigens* because they are large enough to initiate an immune response without binding to another protein.

p-i Concept

Some small-molecular-weight drugs may cause an immune response through a nonhapten pathway.[7–9] Known as the p-i concept, this pathway involves a direct pharmacologic interaction of drugs with immune receptors that do not require the initial binding of the drug to a carrier protein or processing by antigen presenting cells.[7–9] Based on this theory, drugs can bind to T-cell receptors in a reversible manner, similar to the binding of a ligand to a receptor.[7] It is unknown if the drug binds initially to the T-cell receptor or whether the drug binds first to the MHC molecule on the antigen presenting cell, thereby signaling T-cell activation. The p-i concept is most applicable to the initiation of delayed T-cell-mediated reactions as compared to hapten-initiated immediate immunoglobulin E (IgE) reactions.[7–9]

Altered Repertoire Model

Human leukocyte antigens (HLA) are a set of genetically linked proteins that present antigenic peptides to T cells during an immune response.[10] In the altered repertoire model, a drug positions itself within the HLA peptide-binding groove, thus altering the repertoire and specificity of self-peptide ligands that are bound and presented.[11] Changes in the HLA peptide composition are perceived as foreign which consequently triggers an immune response. This model has been established for abacavir hypersensitivity associated with *HLA-B*5701* polymorphisms and may provide an alternative mechanistic explanation for other HLA-associated drug toxicities.[6,10,11]

EFFECTORS OF ALLERGIC DRUG REACTIONS

Allergic drug reactions can involve most of the major components of the innate and adaptive immune systems, including the cellular elements, immunoglobulins, complement, and cytokines. Although most immunoglobulin isotypes have been implicated in drug allergy, reactions are usually mediated by IgE and activated T cells. IgE bound to basophils or mast cells mediates immediate reactions. Antibodies to other immunoglobulins, such as IgG or IgM, also may be involved in drug allergy, resulting in destruction of cells and tissues. T lymphocytes have a major role in hypersensitivity reactions and are involved in all four types (I–IV) of the DHRs described by Gell and Coombs (see Table e108-1).[2,5,12]

TABLE e108-1

Classification of Allergic Drug Reactions

Type	Descriptor	Characteristics	Typical Onset	Clinical Manifestations
I	Immediate (IgE mediated)	Allergen binds to IgE on basophils or mast cells, resulting in release of inflammatory mediators	Within 1 hour (may be within 1-6 hours)	Anaphylaxis, angioedema, hives, itching, wheezing, hypotension
II	Delayed; cytotoxic	Cell destruction occurs because of cell-associated antigen that initiates cytolysis by antigen-specific antibody (IgG) and complement. Most often involves blood elements	Typically >72 hours to weeks	Hemolytic anemia, thrombocytopenia
III	Delayed; immune complex	Antigen–antibody (IgG or IgM) complexes form and deposit on blood vessel walls and activate complement, which results in a serum sickness-like syndrome or vasculitis	>72 hours to weeks	Serum sickness, fever, rash, lymphadenopathy, joint pain
IV	Delayed; T cell–mediated	Antigens cause activation of T lymphocytes, which release cytokines and recruit effector cells	>72 hours	
	IVa	Th1 cells and interferon-γ, monocytes, and eosinophils respond to the antigen	1-21 days	Tuberculin reaction, contact dermatitis
	IVb	Th2 cells, interleukin-4, and interleukin-5 respond to the antigen	1-6 weeks	Maculopapular rashes with eosinophilia
	IVc	Cytotoxic T cells, perforin, granzyme B, FasL respond to the antigen	4-28 days	Bullous exanthems; fixed drug eruptions
	IVd	T cells and interleukin-8 respond to the antigen	>72 hours	Acute generalized exanthematous pustulosis

Cellular Elements

A variety of cells are involved in drug allergies. The antigen presenting cells, which include macrophages, dendritic cells, and cutaneous Langerhans cells, process the antigenic drug for subsequent recognition by T and B lymphocytes. Basophils and mast cells are instrumental in the development of immediate reactions, whereas eosinophils are recruited in both immediate and nonimmediate reactions. Platelets and vascular endothelial cells are important because they also can release several inflammatory mediators.[13] Most cells of the body, including nerve cells, can become involved directly or indirectly in drug allergy.

Mediators of Allergic Reactions

The release of several preformed, pharmacologically active chemical mediators (eg, histamine, heparin, proteases such as tryptase and chymase, and a variety of other enzymes) is triggered when antigens cross-link IgE molecules on the surface of circulating basophils and tissue mast cells. Newly formed mediators include platelet-activating factor (PAF) and arachidonic acid metabolites (eg, prostaglandins [PGs], thromboxanes, and leukotrienes [LTs]).

Histamine is a low-molecular-weight amine compound formed by decarboxylation of histidine and is stored in basophil and mast cell granules.[14] After the release of these granules following antigen cross linking, tissue effects of histamine are evident within 1 to 2 minutes, but it is rapidly metabolized within 10 to 15 minutes. The major effects of histamine on target tissues include increased capillary permeability, contraction of bronchial and vascular smooth muscles, and hypersecretion of mucous glands. Four classes of histamine receptors (H_1-H_4) are present in varying degrees in organs and tissues. H_1 receptors are most prominent in blood vessels and bronchial and intestinal smooth muscles.

Platelet-activating factor is a glyceride-derived substance that is released by mast cells, alveolar macrophages, neutrophils, platelets, and other cells but not by basophils. It has potent bronchoconstrictor effects and causes platelet aggregation and lysis. It attracts neutrophils and causes their activation. Platelet-activating factor enhances vascular permeability and can cause pain, pruritus, and erythema.

The LTs are metabolites of arachidonic acid produced through the 5-lipoxygenase pathway that have potent effects on bronchial and vascular smooth muscle. Three important LTs, LTC_4, LTD_4, and LTE_4, are produced by basophils or mast cells. These three substances are also referred to as *cysteinyl LTs* and were previously referred to as *slow-reacting substances of anaphylaxis*. The LTs have more potent and longer-lasting bronchoconstrictor effects than histamine and can increase vascular permeability and cause arteriolar vasoconstriction followed by vasodilation. Their effects are slower in onset but longer lasting than those of histamine. Another product, LTB_4, is a potent chemoattractant, particularly for neutrophils. It is also produced by neutrophils, macrophages, and monocytes.

PGs and thromboxanes are metabolites of arachidonic acid produced through the cyclooxygenase (COX) pathway. Some PGs have vasoconstrictive or bronchodilatory properties, while others are vasodilatory or bronchoconstrictive. The major PG product of mast cells is PGD_2. It is a potent inhibitor of platelet aggregation and a bronchoconstrictor. Thromboxanes cause platelet aggregation and are important regulators of coagulation.

The complement system consists of about 30 plasma proteins and is involved in allergy through a variety of immunologic responses, including enhancement of phagocytosis (opsonization of target cells), cell lysis, and generation of anaphylatoxins C3a, C4a, and C5a, which can cause non-IgE-mediated activation of mast cells and release of inflammatory mediators.

CLASSIFICATION OF ALLERGIC DRUG REACTIONS

Immunologic drug reactions are most commonly classified by the system described by Gell and Coombs in 1968.[2,5,12] This system classifies the varied reactions based on the effector cells involved and the timing and clinical presentation of the immune event. The Gell and Coombs classification was developed before our understanding of the varied roles of T cells in the immune response. The original classification system has been adapted to better represent our current understanding of drug allergy (see Table e108-1).[2,5,12]

The ICON expert panel on drug allergy has recommended that drug allergies be classified as *immediate* or *nonimmediate* based on the onset of the reaction. *Immediate* reactions are those culminating in the production of an IgE-mediated response. Immediate reactions typically occur within 1 hour of reexposure to an immunogenic drug and manifest as angioedema, bronchospasm, anaphylaxis, or anaphylactic shock. *Nonimmediate* or delayed drug allergies include a broader category of events; they may occur at least 1 hour after initial drug exposure and up to weeks or months after initial exposure. Nonimmediate reactions are typically mediated by activated T cells and manifest as maculopapular exanthems or delayed urticaria. As noted by the expert panel, this classification system has limitations because the route of drug administration and the presence of immune cofactors (eg, viruses, drug interactions affecting drug metabolism) can influence the onset or progression of the immune reaction.[2]

Immediate (Type I) Reaction

Type I immediate reactions require the presence of IgE specific for the drug's (or drug metabolite's) antigenic determinant. After presentation on MHC molecules and recognition by T cells, the drug immunogen stimulates plasma cells to produce IgE on initial exposure. IgE then binds to basophils and mast cells through high-affinity FcεRI receptors. On repeat exposure to the drug, memory B cells allow for early recognition of the immunogen. Two or more IgE molecules on the basophil or mast cell surface bind to one multivalent antigen molecule (referred to as *cross-linking*), initiating cellular activation. Activation causes the extracellular release of granules with preformed inflammatory mediators, including histamine, heparin, and proteases (tryptase in the mast cell), as well as generation of newly formed mediators, as previously discussed, such as LTs, PGs, thromboxanes, and PAF, among others.

Generation of a type I reaction results in an immediate reaction that may be limited to single organs, typically in the nasal mucosa (rhinitis), respiratory tract (acute asthma), skin (urticaria), or gastrointestinal tract, or they can involve multiple organs simultaneously, termed *anaphylaxis*.

Delayed Type II Reaction

Type II allergic reactions are relatively uncommon and involve the destruction of host cells (usually blood cells) through cytotoxic antibodies by one of two mechanisms. First, the drug binds to the cell (eg, platelet or red blood cell) as a hapten. Antibodies (IgG or IgM) are produced that are specific for the bound drug or a component of the cell surface altered by the drug. The antigen-antibody binding initiates a cytolytic reaction. Cell destruction may be mediated by complement or by phagocytic cells that have antibody Fc receptors on their surfaces. Activation of complement near the cell surface can result in loss of cell membrane integrity and cell death. Alternatively, neutrophils, monocytes, or macrophages may bind to an antibody-coated cell through IgG Fc receptors on their cell surfaces, resulting in phagocytosis of the target cell. The process of enhancement of phagocytosis by antibody binding to cell surfaces or other particles is referred to as *opsonization*. In addition, cell-bound IgG may direct the nonphagocytic action of T cells or natural killer cells, which results in cell destruction by a process called *antibody-dependent cellular cytotoxicity*. This process can proceed in a nonspecific fashion as T cells bind to the target cell through IgG Fc receptors on the T cell surface. Contact between the target and effector cells is necessary.

Cells commonly affected by type II reactions include erythrocytes, leukocytes, and platelets, resulting in hemolytic anemia, agranulocytosis, and thrombocytopenia, respectively. This process may be initiated by drugs such as penicillin, quinidine, quinine, cephalosporins, and sulfonamides.

Delayed Type III Reactions

Type III allergic reactions occur uncommonly and are caused by antigen–antibody complexes that are formed in the blood. The complexes form with drug immunogen and antibody in varying ratios and may deposit in tissues, resulting in local or disseminated inflammatory reactions. Antigen–antibody complex formation can result in platelet aggregation, complement activation, or macrophage activation. Chemotactic substances such as C4a may be produced. These substances cause the influx of neutrophils and result in the release of several toxic substances from the neutrophil (eg, proteinases, collagenases, kinin-generating enzymes, and reactive oxygen and nitrogen substances), which can cause local tissue destruction.

Platelet aggregation may occur as a result of immune-complex formation, resulting in the formation of microthrombi and the release of vasoactive mediators. Also, insoluble complexes may be phagocytized by macrophages and activate these cells.

The formation of antigen–antibody complexes can lead to clinical syndromes such as the Arthus reaction. In this model, a high level of preformed specific IgG antibody combines with antigen to produce a localized edematous, erythematous reaction within 5 to 8 hours. The reaction involves the local formation of insoluble antigen–antibody complexes, complement activation with the release of C3a and C5a collectively referred to as *anaphylatoxins,* mast cell degranulation, and influx of polymorphonuclear cells. Both vasculitis and serum sickness are often the result of Type III reactions.

Delayed Type IV Reactions

Type IV reactions typically manifest as dermatologic events mediated by activated T cells (T helper cell or $CD4^+$; cytotoxic T cell or $CD8^+$).[7,9] Four subclasses of type IV reactions (IVa-IVd) have been described based on the responding T cell (eg, T helper type 1 cell, T helper type 2 cell, cytotoxic T cell), effector mechanism (eg, recruitment of macrophages, eosinophils, or neutrophils), and clinical manifestations (eg, contact dermatitis, bullous exanthems, maculopapular eruptions, pustular exanthems) (see Table e108-1).[2,7,9] Type IV reactions require memory T cells specific for the antigen in question. On exposure to the antigen, the immune response is mediated by a specific subtype of T cell that orchestrates an inflammatory response through the secretion of cytokines and the recruitment of effector cells. These reactions are associated with a wide variety of adverse effects, and they also may be useful for diagnostic purposes. Examples of the latter include the purified protein derivative (PPD) antigen from *Mycobacterium tuberculosis* used in the tuberculin skin test and other recall skin test antigens, such as mumps. After intradermal injection, these antigens produce a local reaction (erythema and induration) within 48 to 72 hours. Delayed contact hypersensitivity and maculopapular rashes frequently result from a Type IV reaction.

Other Allergic Reactions

Not all drug allergies can be classified with the system described by Gell and Coombs because the precise immune drug mechanism may not be known. In some cases, hepatic drug reactions (cholestatic or hepatocellular) and pulmonary reactions (eg, nitrofurantoin-associated interstitial pneumonitis) have been described as immune events. Perhaps most common are the delayed dermatologic reactions that occur with a variety of drugs (especially penicillins and sulfonamides). These reactions may be evident as fixed drug eruptions; maculopapular, morbilliform, or erythematous rashes; exfoliative dermatitis; photosensitivity reactions; or eczema. These reactions also may manifest as late-onset pruritus, urticaria, and angioedema.

Some serious cutaneous adverse reactions (SCARs) may be the result of immunologic reactions. SCARs include drug rash with eosinophilia and systemic symptoms (DRESS) and mucocutaneous disorders, SJS and toxic epidermal necrolysis (TEN) (see Fig. e108-1). Both SJS and TEN are purported to result from a T cell response leading to keratinocyte apoptosis. Cytotoxic T cells stimulated in response to the drug immunogen activate caspases, intracellular proteases that can cleave a key intracellular protein in the keratinocyte resulting in apoptosis.[15] The caspase cascade may be activated by two T-cell-mediated pathways: the Fas-FasL pathway and the perforin-granzyme pathway.[16] The blister fluid of patients with SJS/TEN has contained concentrations of FasL, perforin, and granzyme B that correlated with the severity of the events. Overexpression of tumor necrosis factor-β, IL-2, and IL-5 has also been seen in skin lesions of patients with SJS and TEN.

Drug Hypersensitivity Reactions

Based on the new terminology, DHRs include adverse drug reactions that clinically resemble drug allergy but have not yet been proven to be associated with an immune response. Various drugs can produce reactions that are clinically similar to drug allergy, both immediate and delayed in onset, but are not mediated by immune mechanisms. Drugs can cause the release of mast cell–derived and basophil-derived mediators by a pharmacologic or physical effect rather than through cell-bound IgE. Nonimmune DHRs refer to a wide array of reactions ranging from localized hives to life-threatening angioedema, hypotension, and anaphylaxis, all of which are explained by the nonimmunologic release or activation of inflammatory mediators.[2] Drugs that can produce a nonimmune DHR include vancomycin, opiates, iodinated radiocontrast agents, angiotensin-converting enzyme (ACE) inhibitors, amphotericin B, and D-tubocurarine. A vancomycin infusion reaction is a common example of a DHR. If vancomycin is infused too rapidly, it can cause the direct release of histamine and other mediators from cutaneous mast cells, producing a clinical picture of itching, flushing, and hives, first around the neck and face and then progressing to the chest and other parts of the body, usually beginning shortly after the infusion has begun. In some cases, the cutaneous manifestations of vancomycin infusion reactions may be accompanied by hypotension, thereby constituting an immediate DHR. Most patients who have had infusion-related reactions will tolerate vancomycin if the rate of infusion is slowed. In rare cases, the severity of the reaction may preclude continued therapy with vancomycin. Some agents (including aspirin) may produce nonimmune DHRs by altering the metabolism of inflammatory mediators such as PGs or kinins. Angioedema from ACE inhibitors or sacubitril, a neprilysin inhibitor, are classic examples of nonimmune DHRs. With these agents, angioedema results from pharmacologic inhibition of the breakdown of bradykinin, leading to inflammation, increased vascular permeability, and vasodilation.

CLINICAL MANIFESTATIONS OF ALLERGIC DRUG REACTIONS

Anaphylaxis

③ Anaphylaxis is an acute, life-threatening reaction, usually mediated by an immune mechanism, that involves multiple organ systems and occurs in 10 to 20 per 100,000 population per year.[17] About 1,500 deaths from anaphylaxis occur annually in the United States.[18] The lifetime prevalence of anaphylaxis (estimated at 1.6%-5.1%) is rising, most notably in association with the increased use of biologic agents and in the younger age group due to food allergies. Although many drugs may cause anaphylaxis, the most commonly reported are penicillins, aspirin and other NSAIDs, and insulins.[3,19] In most patients, the initial signs and symptoms occur in the skin (flushing, pruritus, urticaria, and angioedema). The second most common symptoms are respiratory (tightness of the throat and chest, dysphagia, dysphonia and hoarseness, cough, stridor, shortness of breath, dyspnea, congestion, rhinorrhea, and sneezing) followed by dizziness, hypotension, and gastrointestinal symptoms (nausea, cramping abdominal pain, vomiting, and diarrhea).[19] About 10% to 30% of patients develop hypotension. Additional cardiovascular effects include syncope, altered mental status, chest pain, and dysrhythmia.[17]

A consensus panel on allergy has defined anaphylaxis as highly likely when one of the following three scenarios is present[19]:

1. Acute onset of a reaction (minutes to several hours) that involves the skin (mucosal tissue) and the respiratory tract and/or a decrease in blood

pressure.

2. The rapid onset of a reaction after exposure to a likely allergen that involves two organ systems (respiratory tract, skin, cardiovascular, and/or gastrointestinal).
3. A decrease in blood pressure alone after exposure to a known allergen.

The panel indicated that other presentations may manifest as anaphylaxis, such as acute chest pain or arrhythmia without dermatologic manifestations, and that the potential exists for false-positive results.

Anaphylaxis generally begins within 1 hour but almost always within 2 hours of exposure to the inciting allergen. The risk of fatal anaphylaxis is greatest within the first few hours. Late phase or "biphasic reactions" can occur 1 to 72 hours after the initial presentation with most occurring within 6 hours. Because of the possibility of a biphasic reaction, for patients with a severe initial presentation of anaphylaxis (hypotension, multiple doses of epinephrine, or other markers of severity), extended observation should be considered (≥ 6 hours).[19] Fatal anaphylaxis most often results from asphyxia caused by airway obstruction either at the larynx or within the lungs. Cardiovascular collapse may occur as a result of asphyxia; in other cases, cardiovascular collapse may be the dominant manifestation from the release of mediators within the heart muscles and coronary blood vessels.

Clinical markers may aid in the diagnosis of anaphylaxis. Serum concentrations of tryptase or mature tryptase (also known as β-tryptase) peak within 0.5 to 2 hours after the onset of anaphylaxis.[19] Tryptase concentrations are most helpful in making the diagnosis if they are drawn no more than 6 hours after the onset of symptoms. Since plasma histamine concentrations remain elevated for only 30 to 60 minutes, they are not clinically useful in patients who present 1 hour or later after the onset of anaphylaxis.[19]

Serum Sickness and Serum Sickness–Like Disease

Serum sickness is a clinical syndrome resulting from the effects of soluble circulating immune complexes that form under conditions of antigen excess. The reaction commonly results from the use of antisera containing foreign (donor) antigens such as equine serum in the form of antitoxins or antivenoms. The onset of serum sickness is usually 7 to 14 days after antigen administration. The onset may be more rapid with reexposure to the same agent in an individual with prior serum sickness. Fever, malaise, and lymphadenopathy are the most common clinical manifestations. Arthralgias, urticaria, and morbilliform skin eruption also may be present. A milder and more transient form of serum sickness is serum sickness–like disease (SSLD). The predominant feature of SSLD is a cutaneous eruption, either urticarial or maculopapular, that occurs within 5 to 21 days of drug administration. As with serum sickness, the rash is usually preceded by a prodromal phase consisting of fever, malaise, lymphadenopathy, and arthralgias. SSLD has been associated with the administration of ciprofloxacin, bupropion, hydantoins, minocycline, sulfonamides, penicillins, and cephalosporins (especially cefaclor). SSLD is usually self-limiting after discontinuation of the causative agent, but it can sometimes progress to vasculitis.

Drug Rash with Eosinophilia and Systemic Symptoms

Previously known by the term *drug hypersensitivity syndrome*, the triad of rash, eosinophilia, and internal organ involvement is referred to as DRESS (see Fig. e108-1). The criteria for a diagnosis of DRESS are as follows: (a) cutaneous drug eruption (usually a diffuse maculopapular rash accompanied by facial and neck edema); (b) hematologic abnormalities including eosinophilia greater than 1,500 cells/mm^3 (1.5 × 10^9/L) or the presence of atypical lymphocytes; and (c) systemic involvement including adenopathies greater than 2 cm in diameter, hepatitis, interstitial nephritis, interstitial pneumonia, or carditis. Both the allopurinol hypersensitivity syndrome and anticonvulsant hypersensitivity syndrome are examples of DRESS.[20] Other drugs associated with DRESS include vancomycin, minocycline, dapsone, lamotrigine, and sulfonamides.[21] The onset of DRESS is typically delayed ranging from 3 to 8 weeks after drug initiation and the clinical manifestations (targeted organs and the severity of organ involvement) can vary between patients.[21] The mortality rate associated with DRESS is 10%, and it is largely attributed to the systemic involvement of the liver, kidneys, or lungs.[20] After discontinuation of the causative drug, the skin rash resolves and laboratory abnormalities normalize over 4 to 8 weeks. Systemic corticosteroids (0.5-1 mg/kg/day prednisone or steroid equivalent) have been used in the treatment of DRESS based on the severity of organ involvement.

Drug Fever

Fever may occur in response to an inflammatory process or develop as a manifestation of an adverse drug reaction. Drug fever has been estimated to occur in as many as 10% of hospital inpatients and is a diagnosis made after excluding other known causes of fever.[22] Many drugs have been reported to cause fever with the most frequently implicated classes being antimicrobials (eg, acyclovir, amphotericin B, β-lactams, minocycline, rifampin, sulfonamides, and tetracycline), anticonvulsants (eg, carbamazepine and phenytoin), antiarrhythmics (eg, procainamide and quinidine), and other cardiac medications (eg, clofibrate, diltiazem, dobutamine, furosemide, heparin, methyldopa, and procainamide).[22] These drugs may affect the central nervous system (CNS) directly to alter temperature regulation or stimulate the release of endogenous pyrogens (eg, interleukin-1 and tumor necrosis factor), PGs, or nervous system monoamines that alter the thermoregulatory set point.[22] Drugs also may cause fever as a result of their pharmacologic effects on tissues (eg, fever resulting from massive tumor cell destruction caused by chemotherapy).

The temperature pattern of drug-induced fever is quite variable and therefore of little help in the diagnosis. Four patterns of drug fever have been described: continuous, remittent, intermittent, and hectic. A combination of intermittent and remittent, hectic fever is the most common pattern with temperatures of 102°F to 104°F (38.9°C–40.0°C) interrupting normal temperatures throughout the day.[22] Drug fever may occur at any time during therapy with a median reported time of 7 to 10 days after drug initiation. Antimicrobials and antineoplastic drugs have been associated with the shortest time to onset (median, 6 and 0.5 days, respectively), whereas CNS agents and cardiovascular drugs have longer times to onset (median, 10 and 16 days, respectively).[22] Laboratory findings such as leukocytosis, eosinophilia, elevated lactic dehydrogenase, and elevated erythrocyte sedimentation rate may aid in the diagnosis. Withdrawal of the causative agent usually results in prompt defervescence. Fever usually recurs upon readministration of the causative agent.

Drug-Induced Autoimmunity

Autoimmune diseases have been associated with drugs and may involve a variety of tissues and organs. A commonly recognized drug-related autoimmune disorder is systemic lupus erythematosus (SLE) induced by infliximab, etanercept, procainamide, hydralazine, quinidine, or isoniazid (see Chapter 107).[23] Exposure of susceptible persons to these agents alters normal body proteins, RNA, or DNA in such a way as to make these components antigenic, leading to the formation of autoreactive antibodies and cells. Most patients treated with infliximab develop antinuclear antibodies, but only 2% of patients present with SLE symptoms. The most common clinical manifestations include arthralgias, myalgias, and polyarthritis. Facial rash, ulcers, and alopecia occur less frequently. Renal or pulmonary involvement also may occur. These reactions typically develop several months after beginning the drug and generally resolve soon after the drug is discontinued.

Other syndromes believed to involve autoimmune mechanisms include drug-induced hemolytic anemia attributed to methyldopa, interstitial nephritis produced by nafcillin/oxacillin, and hepatitis caused by phenytoin and halothane. Interstitial nephritis is characterized by fever, rash, and eosinophilia associated with proteinuria and hematuria. The presence of urine eosinophils helps make the diagnosis, but their absence does not rule out interstitial nephritis. Hepatic damage due to drugs generally is manifested as either hepatocellular necrosis or cholestatic hepatitis. Drug-induced hepatitis has been associated with phenothiazines, sulfonamides, halothane, phenytoin, and isoniazid (see Chapter e56). Hepatocellular destruction is evidenced by elevations in serum transaminases. Hepatomegaly and jaundice sometimes may be evident. Cholestasis may be manifested by jaundice and elevations in serum alkaline phosphatase and sometimes by rash, fever, and eosinophilia.

Vasculitis

Vasculitis is a clinicopathologic process characterized by inflammation and necrosis of blood vessel walls. The vasculitic process may be limited to the skin, or it may involve multiple organs, including the liver or kidney, joints, or CNS. Cutaneous vasculitis is usually manifested by purpuric lesions that vary in size and number. Vasculitis also may be manifested as papules, nodules, ulcerations, or vesiculobullous lesions, generally occurring on the lower extremities but sometimes on the upper extremities, including the hands. Drugs associated with vasculitis include allopurinol, β-lactam antibiotics, sulfonamides, thiazide diuretics, phenytoin, and vancomycin.

Serious Cutaneous Reactions

Although most dermatologic reactions are mild and resolve promptly after drug discontinuation, SJS and TEN are serious or even life-threatening reactions (see Fig. e108-1). Both SJS and TEN are classified as progressive bullous or "blistering" disorders that constitute dermatologic emergencies.[24] They are considered severe variants of erythema multiforme. Similar to erythema multiforme, SJS and TEN are associated with the widespread development of a variety of skin lesions, including macules, purpuric lesions, and the target iris lesion. The target lesion is discrete and round and identified by an area of central clearing surrounded by two concentric rings of edema and erythema. Unlike erythema multiforme, SJS and

TEN are most often drug-induced rather than associated with recurrent herpes simplex viral infection, and they progress to include mucous membrane erosion and epidermal detachment.[24] Mucosal membranes in the mouth, lips, nasal cavity, and conjunctivae are usually involved. As these syndromes progress, the erythematous lesions become more widespread on the face, trunk, and extremities, and many evolve into blisters. Within days after the onset of the lesions, full-thickness epidermal detachment occurs. SJS and TEN are often considered as a continuous spectrum of a disease, with TEN being the most severe form. The extent of epidermal detachment is used to distinguish between SJS and TEN (eg, less than 10% detachment of body surface area with SJS; greater than 30% detachment of body surface area with TEN). The term *SJS-TEN overlap* is used to describe cases in which epidermal detachment occurs on 10% to 30% of the body surface area.[24] Both SJS and TEN are associated with long-term sequelae, including permanent visual impairment, temporary nail loss, cutaneous scarring, and irregular pigmentation. As the more severe form, TEN is also more likely to be complicated by systemic organ involvement, including acute kidney failure, neutropenia, and respiratory failure. A severity-of-illness scoring system known as SCORTEN has been developed to predict prognosis in patients with TEN.[25] SCORTEN uses seven independent risk factors based on an assessment within 24 hours of clinical presentation.

TEN is estimated to occur in 0.4 to 1.3 cases per 1 million people per year, and SJS has been reported in 1 to 6 cases per 1 million people per year.[26,27] The mortality rates associated with SJS and TEN range from 1% to 5% and 10% to 70%, respectively.[27] Antimicrobials are implicated most frequently as the cause of cutaneous events with reaction rates ranging from 1% to 8%. The most likely offenders of SJS and TEN are the sulfonamides, particularly trimethoprim–sulfamethoxazole.[28] Other major offenders of SJS and TEN identified in these studies are allopurinol, aminopenicillins, carbamazepine, cephalosporins, imidazole antifungals, lamotrigine, nevirapine, oxicam NSAIDs, phenytoin, quinolones, and tetracyclines.[28] Cutaneous manifestations of SJS or TEN are often preceded several days by fever with or without flu-like symptoms. Therefore, early discontinuation of the offending medication in patients who have these early signs and symptoms before cutaneous manifestations may prevent disease progression.

Respiratory Reactions

Drugs may produce upper or lower respiratory tract reactions, including rhinitis and asthma. Respiratory tract manifestations may result from direct injury to the airways or may occur as a component of a systemic reaction (eg, anaphylaxis). Asthma may be induced by aspirin and other NSAIDs or by sulfites used as preservatives in foods and medications. Other pulmonary drug reactions believed to be immunologic include acute infiltrative and chronic fibrotic pulmonary reactions. The latter is often caused by antineoplastic agents such as bleomycin. See Chapter e48 for a more detailed discussion of drug-induced pulmonary disease.

Hematologic Reactions

Most formed elements and soluble components of the hematopoietic system may be affected by immunologic drug reactions. Eosinophilia is a common manifestation of drug hypersensitivity and may be the only presenting sign. Hemolytic anemia may result from hypersensitivity to drugs. Other hematologic reactions include thrombocytopenia, granulocytopenia, and agranulocytosis (see Chapter e125).

FACTORS RELATED TO THE RISK OR SEVERITY OF ALLERGIC DRUG REACTIONS

④ Among the factors that influence the likelihood of drug allergy are the degree to which the drug and its metabolites bind covalently to human proteins, how the drug is metabolized, whether the drug contains proteins of nonhuman origin (eg, chimeric monoclonal antibodies, and streptokinase) or antigenic excipients (eg, peanut oil, FD&C dyes, sulfites, and soybean emulsion), the route of exposure, and the sensitivity of the individual as determined by genetics and environmental factors. Hypersensitivity can occur with any dose of a drug, but sensitization is more likely to occur with continuous dosing rather than single dosing. After a patient has become sensitized, the severity of a reaction is often determined by the dose and the duration of exposure. The route of administration may also influence drug sensitivity. The topical route of drug administration is the most likely to sensitize and predispose to drug reactions. The oral route is the safest, and the parenteral route is most hazardous for the administration of drugs in sensitive individuals. Relatively few cases of immediate hypersensitivity-associated deaths with oral β-lactam antimicrobials have been reported.

The presence of genetically determined HLA alleles increases susceptibility to several drug hypersensitivity syndromes. In patients infected with the human immunodeficiency virus (HIV), hypersensitivity to abacavir has been associated with the presence of *HLA-B*5701*.[29] Severe immune-mediated cutaneous reactions to allopurinol, including SJS and TEN, have been associated with the presence of *HLA-B*5801* in Han Chinese.[30] In this same patient population, the presence of *HLA-B*1502* increases the risk of SJS and TEN with carbamazepine, phenytoin, and fosphenytoin.[31] *HLA-A*3101* has been related to the development of nonblistering DHRs such as DRESS to carbamazepine in European and North Asian populations.[32] Associations between HLA alleles and drug reactivity have been described for aminopenicillins, aspirin, iodinated contrast media, gold, lamotrigine, and trimethoprim–sulfamethoxazole.[33] In patients with a history of immediate reactions to β-lactam antibiotics, a single nucleotide polymorphism of HLA-*DRA*, an MHC Class II gene, was a predictor of skin test positivity to amoxicillin and other penicillins but not cephalosporins.[34] Genetic factors can also influence the metabolic deactivation of drugs via phase 1 and 2 metabolisms. For example, slow acetylators of procainamide and hydralazine are at increased risk for SLE. A genetic variant in *CYP2C*, notably *CYP2C9*3*, was associated with phenytoin-induced SCARs.[35] Genes also encode for the type of T cell receptor and the specific cytokines involved in allergic drug reactions.

Drug allergies develop with equal frequency in atopic and nonatopic individuals. In addition, patients with a history of drug allergy are at increased risk for adverse reactions to other pharmacologic agents. Age seems to be related to the risk of allergic reactions because they occur less frequently in children and elderly adults. This may be related to immaturity of the immune system or naturally waning of the immune system over time, also referred to as *immunosenescence*. The presence of some concurrent diseases, particularly viral infections, predisposes to drug reactions. Examples include the higher rate of morbilliform rash when ampicillin is administered to patients with infectious mononucleosis, the higher rate of reactions to trimethoprim–sulfamethoxazole in HIV-infected patients, and the relationship between infection with human herpesvirus 6 (HHV-6) and the development of DRESS.

DRUGS COMMONLY ASSOCIATED WITH ALLERGIC DRUG REACTIONS

Antimicrobials

β-Lactams

About 8% of individuals in the United States healthcare system report an allergy to penicillin and 1% have a noted cephalosporin allergy.[36] Avoidance of penicillins in patients with self-reported allergy is a growing health concern. The use of alternative antibiotics in these patients is associated with increased medical costs and an increased frequency of infection with methicillin-resistant *Staphylococcus aureus* (MRSA) and *Clostridioides difficile*.[37] Only 10% to 20% of patients reporting penicillin allergy have a positive skin test.[3,38] Patients with a history of immediate penicillin allergy who have a negative penicillin skin test (PST) result are unlikely to react on subsequent courses of penicillins.[3,38]

The most common reactions to penicillin include urticaria, pruritus, and angioedema. All four of the major types of allergic reactions described in the Gell and Coombs classification scheme have been reported with penicillin, as well as some reactions that do not fit into these categories. A wide variety of idiopathic reactions occur, such as maculopapular eruptions, eosinophilia, SJS, and exfoliative dermatitis. Cutaneous reactions can occur in up to 4.4% of treatment courses of penicillin and up to 8% of those of aminopenicillins.[39] The incidence of a rash is close to 100% in patients receiving ampicillin with viral infections such as infectious mononucleosis.

Some aspects of the mechanism of penicillin immunogenicity have been determined. As a relatively small molecule (356 Da), benzylpenicillin must combine with macromolecules (presumably proteins) to elicit an immune response. Penicillin is rapidly hydrolyzed to several reactive metabolites that can covalently link to proteins. Of these metabolites, 95% is in the form of benzylpenicilloyl that binds covalently to the lysine residues of proteins such as albumin through an amide linkage involving the β-lactam ring (see Fig. e108-2). This penicilloyl–protein conjugate is referred to as the *major antigenic determinant*. The other penicillin metabolites such as penilloate and penicilloate bind in lesser quantities to proteins. These are referred to as *minor antigenic determinants*. The terms *major* and *minor* refer to the relative proportions of these conjugates that are formed and not to the clinical severity of the reactions generated. Immediate hypersensitivity reactions may be mediated by IgE for both minor and major determinants. The minor antigenic determinants are more likely to cause life-threatening anaphylactic reactions.

In addition to the major and minor determinants, unique side-chain determinants may mediate allergy to some penicillins. The frequency of reactions to the β-lactam core of penicillin, as determined via skin testing, is decreasing while reactions to the R-group side chains of the penicillins are increasing.[40] Both the aminopenicillins and piperacillin may cause hypersensitivity reactions via their unique side chains.[41] Therefore, a patient may exhibit hypersensitivity to amoxicillin or piperacillin via a side chain determinant while exhibiting no reactivity to other penicillins. Reports of selective allergy to amoxicillin have become relatively common. The R-group side chain of amoxicillin is believed to be the primary epitope, but selective reactivity to clavulanic acid has been postulated and evaluated in those experiencing a reaction to amoxicillin/clavulanate.[42,43] Careful history taking is needed to identify patients with a high likelihood of side-chain–specific reactions. Skin testing with dilute concentrations of amoxicillin, ampicillin, and piperacillin has been used to aid in the determination of side-chain–specific reactions.[44–46]

Patients who are allergic to penicillins also may be sensitive to other β-lactams. The exact incidence of cross-reactivity between cephalosporins and penicillins is not known but is believed to be low.[36,47] The risk was originally reported as 10% to 15% in the 1970s when cephalosporins were contaminated with trace amounts of penicillin. Current estimates of the cross-reactive risk between penicillin and the first- and second-generation cephalosporins are 5% to 7.5% and as low as 1% between penicillin and the third- and fourth-generation cephalosporins.[3] One percent to 8% of patients with penicillin-specific IgE may develop an immediate-type hypersensitivity reaction to cephalosporins.[48] In contrast, patients with reported penicillin allergy and negative skin test results are at no greater risk than the general population.[3]

⑤ Ideally, cephalosporins should be avoided in patients with a history of a severe, immediate hypersensitivity reaction to penicillin, although most studies report a low risk of an allergic response to a cephalosporin even in a person with a positive skin test result to penicillin. Patients with penicillin allergy have the highest risk of cross-reactivity with the first-generation cephalosporins (odds ratio [OR] 4.79; 95% confidence interval [CI] 3.71-6.17).[49] The odds of reacting to a second- and third-generation cephalosporin were 1.13 (95% CI 0.61-2.12) and 0.45 (95% CI 0.18-1.13), respectively.[49] The higher rate of cross-reactivity between penicillin and the first-generation cephalosporins has been attributed to similarities in the R1 side chains of these agents.[3,46] The R1 side chain is connected to the opened β-lactam ring, thereby influencing the antigenicity of these agents. When assessing the potential for cross-reactivity between penicillins and cephalosporins, clinicians should evaluate the similarities in the R1 side chains of the agents.[46,49,50] β-lactam antibiotics with an R1 substitution chemically similar to that of penicillin G are cephalothin and cefoxitin. In the R1 position, amoxicillin is chemically similar to ampicillin, cefaclor, cephalexin, and cefadroxil.

Cephalosporins rarely induce immune responses mediated by the core β-lactam structure, but they are more likely to do so via unique R-group side-chain determinants.[49] In a patient with a cephalosporin allergy, skin testing with the major and minor determinants of penicillin can be used to identify the likelihood of reactivity to the core β-lactam ring. The risk of cross-reactivity between cephalosporins is higher than that between the penicillins and cephalosporins. Cross-reactions may occur through identical R1 side chains. Of note, ceftazidime and cefiderocol share a common side chain with aztreonam.

The actual risk of a cross-reaction between the penicillins and the carbapenems is much lower than originally described. The initial estimate of the cross-reactive risk was 47.4%, but current estimates range from 0.9% to 11%.[47] The initial estimate was based on the results of skin testing with penicillin and nonstandardized carbapenem reagents. Several retrospective studies reporting variable rates of cross-reactivity relied on self-reported histories as confirmation of penicillin allergy. In four published prospective studies, both skin testing methods and carbapenem challenge dosing were used to assess cross-reactive risk. In one of these studies, only one of 112 patients with skin test–confirmed penicillin allergy had a positive skin test result for imipenem.[51] Challenge dosing with imipenem to a final dose of 500 mg was subsequently performed in 110 patients with negative imipenem skin test results; none of the 110 patients had a reaction. Results of two additional prospective studies, one of which was performed in children aged 3 to 14 years, suggest a low risk of cross-reactivity between penicillin and meropenem.[52,53] In both studies, only one patient with skin test-positivity to penicillin had a positive skin test result for meropenem. Graded challenge dosing with meropenem was tolerated in 100% of the skin test–negative patients in both studies. In another study, 212 patients with a skin test positive to penicillin underwent skin testing with ertapenem, meropenem, and imipenem.[54] None of the 212 patients had skin test positivity to a carbapenem. Graded challenge to a full therapeutic dose of each carbapenem was subsequently performed in 211 subjects.[54] No patient exhibited a reaction during challenge dosing. Based on these results, the routine practice of avoiding carbapenem use in patients with a history of penicillin allergy should be reconsidered.

Of the monobactams, aztreonam only weakly cross-reacts with penicillin and can be administered safely to most patients who are penicillin allergic.[3,47] In 211 patients with a positive skin test to a penicillin, graded challenge dosing to a full therapeutic dose of aztreonam was uneventful in all patients.[54]

Sulfonamides

Sulfonamide drugs containing the sulfa (SO_2NH_2) moiety include antibiotics, thiazide and loop diuretics, oral hypoglycemics, COX-2 inhibitors, and carbonic anhydrase inhibitors. Other less commonly recognized sulfonamides include antivirals (amprenavir, fosamprenavir, and darunavir), probenecid, tamsulosin, triptans, and zonisamide. Allergic reactions have been reported in 4.8% of 20,226 patients who received a sulfonamide antibiotic and in 2% of patients who received a sulfonamide nonantibiotic.[55] Although immediate IgE-mediated reactions such as anaphylaxis can occur, sulfonamides typically cause delayed cutaneous reactions, often beginning with fever and then followed by a rash (eg, maculopapular or morbilliform eruptions). Infrequently, a seemingly benign maculopapular rash may progress to a mucocutaneous syndrome (eg, SJS or TEN).[4] Other potentially life-threatening reactions to sulfonamides may include hepatic, renal, or hematologic complications.

Immune-mediated sulfonamide reactions depend on reactive metabolites produced in the liver.[56] Trimethoprim–sulfamethoxazole, considered the most highly reactive sulfonamide, contains an arylamine in the N4 position of its chemical structure, allowing for the drug's metabolism to two highly reactive metabolites, a hydroxylamine and a nitroso-sulfonamide.[56,57] Structural differences between the sulfonamide antibiotics and nonantibiotics may influence the metabolic conversion and resultant reactivity of these compounds. Slow acetylator phenotypes may also increase the risk for these reactions. When assessing the potential for allergy to a sulfonamide, the clinician should consider the chemical structure of the agent. Attention should be given to the presence of an arylamine group in the N4 position and/or an N-containing ring attached to the N1 nitrogen of the sulfonamide group.[57]

⑥ Cross-reactivity between sulfonamide antibiotics and nonantibiotics is minimal, with cross-reactivity characterized as "highly unlikely."[58] In one study, about 10% of patients with a history of allergy to a sulfonamide antibiotic subsequently reacted to a sulfonamide nonantibiotic (eg, acetazolamide, loop diuretic, sulfonylurea, and thiazide).[55] This low rate of cross-reactivity has been attributed in part to differences in the chemical structures, and therefore metabolites, of sulfonamide antibiotics and nonantibiotics. The occurrence of allergic reactions after the receipt of sulfonamide nonantibiotics has also been attributed to a predisposition to allergic reactions in the affected individuals rather than cross-reactivity with sulfonamide antibiotics.[55] In one study, cross-reactivity between sulfonamide antibiotics and penicillin was higher than that between the sulfonamide antibiotics and nonantibiotics.[55]

Trimethoprim–sulfamethoxazole is used frequently to prevent or treat *Pneumocystis jirovecii* pneumonia in patients with AIDS or hematologic malignancies. Adverse drug reactions to trimethoprim–sulfamethoxazole occur much more frequently in HIV-positive patients.[59,60] Adverse drug reactions to trimethoprim–sulfamethoxazole occur in 50% to 80% of AIDS patients compared with 10% of other immunocompromised patients.[60] Trimethoprim–sulfamethoxazole was associated with an adverse event rate of 26.3 per 100 person-years and a hypersensitivity event rate of 22 per 100 person-years. Although reactions may include angioedema, SJS, and thrombocytopenia, most reactions to trimethoprim–sulfamethoxazole in HIV-infected patients are delayed and present as a diffuse maculopapular rash with or without fever. The mechanism by which these allergic or allergic-like reactions occur in HIV-infected patients is unclear. It is unlikely that these reactions are IgG or IgE mediated.[61] Proposed mechanisms include alterations in drug metabolism caused by glutathione deficiency, a direct toxic or immunologic effect of the sulfonamide metabolites on body tissues, and increased expression of MHC proteins with increased recognition of the drug antigen by $CD4^+$ and $CD8^+$ cells.[61] The adverse drug reaction rate has been associated with a higher $CD4^+$ T cell count greater than 20 cells/mm^3 (0.020×10^9/L), CD4 to CD8 ratio less than 0.10, and treatment for fewer than 14 days.[60]

Antiretrovirals

Antiretrovirals are commonly implicated in drug hypersensitivity. Early studies suggest HIV-positive patients are one hundred times more susceptible to adverse drug reactions than the general population. The pathophysiology of antiretroviral hypersensitivity in HIV-infected individuals is multifactorial and thought to be related to various drug-disease interactions. Although *in vitro* data supports T-cell-mediated mechanisms, other factors occurring simultaneously, such as the presence of an underlying opportunistic infection, immune reconstitution inflammatory syndrome, and/or initiation of prophylactic antimicrobials with overlapping adverse drug reactions (eg, trimethoprim-sulfamethoxazole), may complicate the clinical diagnosis. A comprehensive history with strong consideration of temporal drug exposure is critical when evaluating antiretroviral hypersensitivity.

A wide range of hypersensitivity reactions has been described with nearly all classes of antiretrovirals. Delayed cutaneous reactions, ranging from self-limiting, mild exanthems to SCAR, are the most common manifestation.[3,62] Systemic features such as fever, rigors, and myalgias are also frequently present. Immediate reactions are rarely reported.

Genetic predisposition may increase the risk of antiretroviral hypersensitivity. For example, the presence of MHC class I allele *HLA-B*5701* significantly increases the risk of abacavir hypersensitivity.[62] Abacavir hypersensitivity syndrome occurs in up to 9% of patients and clinically manifests as fever, constitutional symptoms, and gastrointestinal disturbances with delayed rash occurring in up to 70% of patients. Symptoms generally present within 6 weeks of therapy initiation and resolve within days of therapy cessation.[63] Given these clinical implications, preemptive *HLA-B*5701* screening is recommended before starting therapy.[63] Initiation or continuation of therapy is contraindicated if identified since subsequent reactions may occur more rapidly and may be more severe in nature.[63]

Similar to abacavir, genetic variants of the HLA allele and cytochrome P450 polymorphisms are associated with nevirapine hypersensitivity reactions. Skin rash is observed in 17% to 32% of patients and occurs within 3 months of treatment initiation.[64] Genetic analyses in various patient populations have demonstrated a strong association between the *HLA-B*3505* allele and nevirapine-induced cutaneous reactions, although these data are from small, preliminary analyses.[65] Metabolic variations have also been implicated in nevirapine hypersensitivity reactions. Alterations in cytochrome P450 2B6 (CYP2B6) are associated with higher plasma concentrations of nevirapine which may predispose patients to hepatotoxicity and SCAR.[63,66,67] Irrespective of mechanism, nevirapine hepatotoxicity occurs in 17% to 32% of patients.[64]

Management of antiretroviral hypersensitivities depends on the type and severity of presenting symptoms with special consideration of genetic associations. For mild reactions without systemic organ involvement, symptomatic support with close monitoring may allow for therapy continuation.[62] For patients presenting with more severe phenotypes where alternative options are limited, drug provocation testing, patch testing, and/or desensitization procedures may be considered in a monitored setting, although data supporting these approaches are limited.[62] Desensitization protocols have been described for numerous antiretrovirals including darunavir and efavirenz.[64] Re-exposure to a culprit antiretroviral in patients who experience SCAR or severe drug-induced liver injury is contraindicated. In the case of abacavir, *HLA-B*5701* genetic testing is recommended by guidelines and should be completed before therapy initiation. As previously mentioned, abacavir administration, including via patch testing and desensitization protocols, is contraindicated for patients who are carriers of this HLA allele. Immediate hypersensitivity reactions to antiretrovirals occur rarely. Therefore, standardized approaches in this subgroup of patients have not been established.

Chemotherapeutic Agents

Chemotherapeutic agents are implicated in hypersensitivity reactions in 5% to 15% of patients who receive them. Up to 65% of patients receiving L-asparaginase experience immediate hypersensitivity reactions such as urticaria and anaphylaxis.[68]

The combination of paclitaxel (or docetaxel) and carboplatin is frequently responsible for hypersensitivity reactions. Each agent precipitates a distinct reaction, allowing for differentiation between causative factors. Hypersensitivity or allergy-like reactions have been observed with paclitaxel and docetaxel in as many as 34% of patients.[4,68,69] The reaction typically occurs within minutes after initiation of the first or second dose, suggesting a non-IgE-mediated mechanism. Non-immediate skin reactions can occur from 12 hours to 15 days after exposure. Both of the vehicles of the taxanes (polyoxyethylated castor oil for paclitaxel; polysorbate 80 for docetaxel) and the taxanes themselves have been implicated as the cause of the reactions. A cross-reactive risk of 90% between paclitaxel and docetaxel provides further evidence that the reaction is most likely attributed to the taxane moiety.[70] Severe reactions are characterized by dyspnea, bronchospasm, urticaria, and hypo- or hypertension. Minor reactions include flushing and rashes. In patients receiving a 3-hour infusion, the incidence of severe reactions is reduced to 1.3%, and the incidence of minor reactions is 42%. To reduce the risk of hypersensitivity reactions, patients are routinely premedicated with corticosteroids and both H_1- and H_2-receptor antagonists. A protein-bound formulation of paclitaxel (Abraxane®) devoid of the castor oil vehicle avoids some but not all reactions. Skin testing may determine the safest management approach for patients who experience an immediate taxane-induced hypersensitivity reaction.[71]

Hypersensitivity to platinum-containing agents is delayed, developing after six or more courses of carboplatin, cisplatin, or oxaliplatin, with rates peaking around the eighth or ninth dose.[72–74] The reaction rates differ depending on the platinum agent with reported frequencies of 5% to 20% with cisplatin, 9% to 27% with carboplatin, and 10% to 19% with oxaliplatin.[75] Reactions typically develop shortly after completing the infusion or up to 3 days after therapy. Symptoms of severe reactions include tachycardia, dyspnea, facial swelling, rigors, and hypotension. Mild reactions include itching, erythema, and facial flushing. An association between reactivity and the duration of the platinum-free interval has been described for carboplatin.[76] The risk of a severe reaction was 47% if the platinum-free interval was greater than 24 months versus only 6.5% with intervals less than 12 months.[76] Management strategies include decreasing the rate of infusion and administration of corticosteroids and H_1- and H_2-receptor antagonists.[74] Skin testing can assist in the diagnosis of carboplatin hypersensitivity.[72,75] Given the potential for false-negative skin tests, however, repeat skin testing is recommended for patients with severe or life-threatening histories who have a negative initial skin test result. Desensitization to carboplatin[72,73] and oxaliplatin[77,78] is well tolerated. Antihistamine premedication is recommended before the use of these desensitization protocols to minimize the risk and/or severity of breakthrough reactions.[79]

Biologics

Biologic agents (eg, monoclonal antibodies, fusion proteins, and recombinant proteins) are derived from living sources such as yeast, bacteria, animal cells, or mammalian cells.[80] Unlike nonbiologic agents, these large proteins can serve as complete antigens. Examples include recombinant insulin, erythropoietin, interferon-β, human growth hormone, infliximab, cetuximab, rituximab, and omalizumab. Immunologic reactions to these agents range from minor infusion or injection-site reactions to anaphylaxis. Depending on the agent, reactions can occur on first or subsequent exposure, and the timing may be within 4 hours of drug administration or up to 14 days after an infusion.[80] Both cutaneous and systemic allergic reactions have been reported.

Factors influencing the antigenicity of biologic agents are patient-specific (eg, atopy, congenital protein deficiency), product-specific (eg, presence of contaminants or stabilizing agents, degree of protein glycosylation, presence of nonhuman protein sequences, and storage temperature), and administration related (eg, route of administration, frequency of use, concurrent immunosuppressant use).[80] Of the monoclonal antibodies, reactions are most frequently observed with the murine-derived agents (0% human) and chimeric agents (75% human) as compared to the humanized (greater than 90% human) and human (100% human) agents. Some immune reactions to biologic agents result from the development of neutralizing antibodies that can prevent the protein from exerting its intended effect. Neutralizing antibodies can mediate reactions to interferon-β_{1b} and β_{1a}, infliximab, natalizumab, recombinant factor VIII, and recombinant factor IX.[80] Anti-infliximab antibodies, which occur in up to 60% of treated patients, are associated with a higher frequency of infusion reactions and decreased therapeutic effect.[81] Concomitant administration of immunosuppressive agents such as prednisone or low-dose methotrexate can decrease the risk of antibody formation to infliximab.[80,81]

Rituximab, a chimeric human-murine IgG_1 monoclonal antibody directed against the CD20 antigen on surface B cells, is commonly associated with hypersensitivity reactions. More than 75% of patients experience infusion-associated reactions within 24 hours of the first dose. Symptoms reported are consistent with immediate-type reactions, such as urticaria, pruritus, bronchospasms, angioedema, and hypotension.[63,82] Since most infusion reactions only occur upon first exposure, standard administration of subsequent doses is recommended for patients with non-life-threatening reaction histories. Skin testing has also been described and may identify patients with suspected IgE-mediated rituximab hypersensitivity, although the negative predictive value is unknown.

Cetuximab, a human-murine IgG_1 monoclonal antibody directed against epidermal growth factors, presents a unique situation as an allergen.[83] Cetuximab carries a black box warning regarding serious infusion reactions that usually occurred on first dose administration in 3% of patients in pre-marketing studies. Following the approval of the drug, infusion reaction rates as high as 20% were noted in specific regions of the southern United States.[84] These reactions (eg, difficulty breathing, hypotension, shock, loss of consciousness, and/or heart attack) also occurred with the first infusion, but many were severe enough to warrant total discontinuation of therapy. Further investigation of these regional cases revealed a common link: the presence of preexisting IgE antibodies against the oligosaccharide, galactose-α-1,3-galactose (alpha-gal) secondary to lone star tick bites.[85] This oligosaccharide present in the tick is also found on the Fab portion of the heavy chain of cetuximab, resulting in IgE cross-reactions on first drug exposure. Alpha-gal is also present in the serum of nonprimate mammals and may be responsible for delayed hypersensitivity reactions secondary to the ingestion of certain meats.[85] Experience with cetuximab as an immunogen has raised awareness of potential drug-food-environment cross-reactions.

Delayed onset anaphylaxis, ranging from minutes to days post-injection, has been reported with omalizumab, a humanized monoclonal antibody targeted against IgE for the treatment of moderate-to-severe asthma or chronic idiopathic urticaria.[86,87] Although uncommon, occurring in 0.1% to 0.2% of patients, omalizumab carries a black box warning for anaphylaxis. Risk factors include a history of anaphylaxis, regardless of the cause, which increases the risk of an anaphylactic event to 0.6%. Omalizumab-treated patients require observation for 2 hours after the first three injections and 30 minutes after subsequent injections.[88] Patients are advised to carry an epinephrine autoinjector during and for 24 hours after drug administration.[88,89] Inclusion of polysorbate 80 as a stabilizing agent in the formulation and an alteration in the protein sequence via glycosylation may influence the immunogenicity of omalizumab.[87] For select, low-risk patients (eg, no prior history of anaphylaxis; received at least three doses uneventfully; and patient or caregiver is educated and able to recognize and manage signs and symptoms of a severe hypersensitivity reaction), self-administration using a pre-filled auto-injector is now FDA approved.[90]

Management of allergic or DHRs to biologic agents varies based on the culprit agent and the severity and nature of the reaction. Immediate management with epinephrine and permanent discontinuation of the drug may be warranted (eg, omalizumab-induced anaphylaxis). Depending on the biologic agent, reactions may be managed by decreasing the infusion rate (if given intravenously) or by pretreating with antihistamines or corticosteroids. Graded challenge and desensitization protocols for adult and pediatric patient populations to numerous biologic agents have also been described.[75,91,92]

Aspirin and Nonsteroidal Anti-inflammatory Drugs

7 Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) can cause eight general types of DHRs, four of which are related to COX inhibition.[93,94] These DHRs can involve asthma and rhinitis, urticarial/angioedema, anaphylaxis, or pneumonitis. The two most common aspirin sensitivity reactions are respiratory (asthma and rhinorrhea) and urticaria/angioedema in patients without chronic urticaria. Urticaria and angioedema can be IgE- or non-IgE-mediated due to COX-1 inhibition. About 5% of children and 7.2% of adults with asthma are sensitive to aspirin and other NSAIDs.[93–96]

NSAID-exacerbated respiratory disease (NERD), formerly known as aspirin-exacerbated respiratory disease (AERD) and Samter's Triad, refers to a triad of characteristics consisting of asthma, rhinosinusitis with nasal polyps, and acute respiratory tract symptoms upon exposure to aspirin or NSAIDs. This syndrome typically develops in middle-aged patients who are nonatopic and have no history of aspirin or NSAID intolerance. Women are 2.5 times more likely to develop NERD than men.[97] Symptoms usually progress from rhinitis to sinusitis with nasal polyps and moderate-to-severe asthma. It is uncommon in children and young adults. The mechanism of NERD is not completely understood, but it is characterized by overexpression of LTC_4 synthase in the airways.[98,99] In patients with NERD, administration of aspirin and NSAIDs may provoke severe and sometimes fatal asthmatic attacks.

One proposed mechanism of aspirin and NSAID sensitivity is COX-1 blockade, which may facilitate depletion of prostaglandin E_2 (PGE_2) and production of alternative arachidonic acid metabolites (eg, LTs).[93] PGE_2 prevents mast cell degranulation, while LTs cause bronchoconstriction and increased mucus production. Increased LT production may also explain the development of angioedema and urticaria, based on the observed correlation between the degree of COX-1 blockade and the risk of a sensitivity reaction. Therefore, agents such as acetaminophen, which minimally block COX-1, rarely cause reactions. This mechanism is also supported by the clinical observation that LT-modifying drugs can reduce the severity of aspirin-induced asthma and urticaria.[93] It is also possible that aspirin and NSAIDs stimulate mast cells directly to release inflammatory mediators. Patients with NERD may tolerate the selective COX-2–selective inhibitors celecoxib and rofecoxib, as they do not cross-react with aspirin.[100,101]

In patients with aspirin sensitivity (asthma or urticaria) in which aspirin is medically indicated, oral graded challenge dosing and/or desensitization may be tried depending on the clinical history.[102] Several different protocols have been described, and the risk for anaphylaxis cannot be reliably predicted.[93,97,102] Graded challenges should be performed when there is a low clinical suspicion of ongoing aspirin or NSAID sensitivity, while desensitizations are recommended in patients requiring aspirin or NSAIDs, but with a high risk of a repeat reaction. Both graded challenge and desensitization should be performed with caution in a monitored setting with resuscitation equipment at hand. For patients with a history of cutaneous reactions to aspirin, a two-dose challenge of 40.5 mg (one-half of an 81-mg tablet) given 90 minutes apart with no pretreatment has shown promising results.[102] If no reaction occurs after administration of the second dose, the patient may receive 81 mg of aspirin per day for the cardioprotective therapy.[102] In patients with higher risk histories suggestive of a severe IgE-mediated reaction, desensitization protocols have been administered successfully.[63] Management for patients with NERD focuses on treating asthma and nasal polyps with usual therapy and avoidance of aspirin and NSAIDs. However, aspirin desensitization may be indicated, as it improves asthma and nasal polyp burden. These protocols differ from protocols developed for IgE-mediated aspirin allergy. Several oral, bronchial, and nasal aspirin desensitization protocols have been described, ranging from 2- to 4-day protocols for patients with a history of asthma to rapid (2-5 hours) protocols.[3,102,103] For any hypersensitivity reaction, if the oral challenge is not successful and desensitization is not performed, patients with aspirin sensitivity must avoid aspirin and the nonselective NSAIDs.

Individual NSAIDs (eg, ibuprofen, sulindac) and aspirin can cause IgE-mediated allergic reactions. These reactions occur upon re-exposure to the drug and may present as urticarial/angioedema-bronchospasm or anaphylaxis with or without hypotension. A careful and complete allergy history may suggest true allergy to an isolated NSAID. Such patients should be advised to avoid the specific NSAID and any structurally similar NSAIDs (eg, all propionic acid derivatives, all indole acetic acid derivatives) because of the risk of cross-reactivity. Graded challenges can be performed to clarify with NSAIDs are safe to administer. Patients with a history of reacting to a specific NSAID other than aspirin can safely receive aspirin.[102]

NSAIDs have been associated with pulmonary infiltrates and eosinophilia syndrome. Pulmonary infiltrates and eosinophilia syndrome is associated with fever, cough, dyspnea, infiltrates on chest radiography, and peripheral eosinophilia that develops 2 to 6 weeks after initiating treatment. Pulmonary infiltrates and eosinophilia syndrome occurs more frequently for naproxen compared with other NSAIDs and resolves rapidly after the offending agent is discontinued.

Insulin

Insulin can produce an IgE-mediated reaction, an immune complex reaction and delayed T-cell-mediated allergy. The reported prevalence of insulin allergy is 0.1% to 3% and the most common manifestation is an IgE-mediated local reaction at the injection site.[104] Allergic reactions have been reported with bovine and porcine insulin and more rarely with the recombinant human insulin. Insulin's antigenicity may be explained by alterations in protein unfolding during the manufacturing process.[104] Hypersensitivity reactions to insulin have also been associated with additives, such as zinc or protamine, and injection or infusion-related equipment. Development of anti-insulin IgG antibodies occurs commonly after a few months of therapy, but these antibodies remain inactive in most patients.

Local reactions present most often as a wheal and flare at the injection site and may occur immediately after injection or up to 8 to 12 hours later. These reactions are generally mild, do not require treatment, and resolve with continued insulin administration. Before labeling the patient as allergic to insulin, consideration should be given to the patient's insulin administration technique. Systemic antihistamines may be administered in patients who continue to have local reactions, and a different insulin source may be substituted. Systemic reactions to insulin (eg, urticaria or anaphylaxis) rarely occur. For immediate-type reactions, skin testing for insulin preparations used, alternative preparations, and additives is recommended to identify the type of insulin least likely to cause a systemic reaction.[104] For sensitized patients requiring insulin, continuous subcutaneous insulin infusion induction protocols have been administered successfully.[89,105]

Other Agents

Radiocontrast Media

6 Radiocontrast agents frequently cause reactions categorized as immediate (within 1 hour) or nonimmediate (more than 1 hour and up to 10 days) via both IgE-mediated and non-IgE-mediated mechanisms.[88] The frequency and severity of these reactions are influenced by the type of radiocontrast agent (ionic vs nonionic) and patient-specific factors such as history of atopy, asthma, or prior reaction to a radiocontrast agent. The incidence of immediate reactions with ionic and nonionic agents are 1% to 3% and less than 0.5%, respectively.[3,19] Delayed skin reactions, usually presenting as maculopapular exanthems, occur in 1% to 3% of patients over 5 to 7 days.[88] Severe, immediate anaphylactic reactions occur in 0.01% to 0.04% of patients.[88] In addition, radiocontrast agents may cause dose-dependent toxic reactions that can produce renal impairment, cardiovascular effects, and arrhythmias.[106] The mechanism of reactions to radiocontrast agents is not clearly understood. Histamine release and mast cell triggering have been observed in severe immediate reactions, suggesting an IgE-mediated mechanism. The older, high-osmolar radiocontrast agents can activate mast cells, basophils, and the complement system directly (IgE-independent mechanism), resulting in the release of inflammatory mediators. The delayed-onset maculopapular rash appears to be T-cell-mediated. The low-osmolar nonionic contrast agents cause fewer acute reactions.

The risk of immediate reactions to radiocontrast media is greater in women and patients with a history of atopy or asthma.[88] Other recognized risk factors include a history of previous reaction, severe drug allergies, cardiac disease, and treatment with β-blockers.[3,19] Despite a common misconception, seafood allergy or iodine allergy does not predispose to radiocontrast media reactions. Although not recommended in current guidelines, patients with prior immediate reactivity to a radiocontrast agent often undergo skin testing. Skin testing with a panel of different radiocontrast agents may identify a product with low reactive risk.[88] Although some regimens have been recommended to prevent the recurrence of immediate events in patients who have experienced reactions previously, the value of these preventive regimens has not been proven and their use remains controversial.[88,107] A commonly recommended regimen in high-risk patients is prednisone 50 mg orally 13, 7, and 1 hours before exposure with diphenhydramine 50 mg orally or intramuscularly 1 hour before exposure to prevent immediate reactions.[19] Ephedrine 25 mg orally has also been recommended 1 hour before the radiocontrast study as a component of the pretreatment regimen, but ephedrine should not be used if the patient has a history of unstable angina, hypertension, or arrhythmia.[3,19] Other studies have examined the use of H_1- and H_2-antihistamines, clemastine, or cimetidine, respectively.[3,19]

Immediate reactions to gadolinium, a noniodinated contrast agent, have been reported at frequencies of 0.07% in adults and 0.04% in children.[108] Most reactions have been mild, requiring either no medical management or treatment with antihistamines. Moderate and severe reactions have also been rarely reported. Pretreatment regimens similar to those used with iodinated contrast studies are usually effective, but they have been associated with breakthrough reactions, particularly in patients with a history of reactions to gadolinium or iodinated contrast agents.[109]

Pharmaceutical Excipients and Additives

Pharmaceutical products contain many “inert” additives (eg, dyes, fillers, buffers, and stabilizers) in addition to the therapeutic ingredients. These additives are not always inert and may cause adverse effects, including allergic reactions. Excipients that may cause allergic reactions include benzyl alcohol, carboxymethylcellulose, povidone, dyes, sodium benzoate, sulfites, and polyethoxylated surfactants.[110] Identification of additives and excipients as causes of allergic reactions are typically performed by the process of elimination.

Anticonvulsants

Many anticonvulsant drugs produce a variety of DHRs. Drugs such as phenytoin, phenobarbital, carbamazepine, and lamotrigine can cause an “anticonvulsant hypersensitivity syndrome” characterized by a triad of symptoms including fever, rash, and internal organ involvement. Lymphadenopathy and eosinophilia are frequently present and many reactions meet the definition of DRESS. The onset usually occurs several weeks into therapy.[32] In some cases, morbilliform rash develops into exfoliative dermatitis. The risk of cross-reactivity between the aromatic anticonvulsants (eg, carbamazepine, phenobarbital, and phenytoin) ranges from 40% to 80% and is associated with specific genetic predispositions.[32] A genetic marker for severe reactions to carbamazepine, phenytoin, fosphenytoin, and lamotrigine is the presence of the *HLA-B*1502* allele.[31] This allele is found in 10% to 15% of patients from China, Thailand, Malaysia, Indonesia, the Philippines, and Taiwan. In a population of patients from Taiwan, Japan, and Malaysia, genetic variation in the *CYP2C* gene, notably *CYP2C9*3*, was associated with phenytoin-induced SCARs (OR 11; 95% CI 6.2-11.8).[35]

Oxcarbazepine, the 10-keto derivative of carbamazepine, has exhibited both in vitro and in vivo cross-reactivity with carbamazepine. The concomitant use of valproate with lamotrigine significantly increases the risk of DHRs because of reduced lamotrigine metabolism, leading to a prolonged elimination half-life.

ACE Inhibitors and Angiotensin-Receptor Blockers

ACE inhibitor-associated angioedema occurs in 0.2% to 1% of treated patients.[111] It usually involves the face, tongue, lips, and pharynx but may also extend to the lower gastrointestinal tract. ACE is a nonspecific dipeptidase that not only inhibits the conversion of angiotensin I to angiotensin II but is also involved in the inactivation of bradykinin, substance P, and neurokinin A. High levels of bradykinin and substance P have been associated with vasodilation, increased vascular permeability, and inflammation resulting in angioedema in susceptible patients. The prevalence of ACE inhibitor–induced angioedema is highest in women and African American patients.[111] An added risk factor is the concomitant use of medications that inhibit bradykinin metabolism, such as the neprilysin inhibitor, sacubitril. Current labeling for the sacubitril/valsartan combination product provides a cautionary recommendation for a 36-hour washout period when converting to or from an ACE inhibitor.[112]

Angioedema secondary to angiotensin-receptor blockers (ARBs) has been reported; the weighted incidence was 0.11% in a meta-analysis of 35,000 patients treated with an ARB.[113] The mechanism by which ARBs cause angioedema is poorly understood. The risk of a “cross-reaction” between ACE inhibitors and ARBs is not clear. ARBs may cause repeat events through an independent mechanism or through a common pathway not yet determined. Based on a systematic review of 71 patients, the risk of subsequent angioedema after switching to an ARB was 9.4% for possible cases and 3.5% for confirmed cases.[114] None of the events were fatal. Before switching to an ARB in patients with a history of ACE inhibitor–related angioedema, consideration must be given to the severity of the initial event (eg, isolated nondiffuse facial swelling vs diffuse angioedema with laryngeal inflammation, esophageal or intestinal involvement), the prior responsiveness to treatment for angioedema and the benefit to risk ratio of ARB use in the patient.

Chlorhexidine

The prevalence of allergy or DHRs to chlorhexidine is not known, but cases ranging from anaphylaxis to contact dermatitis have been increasingly reported over the past 10 years.[115] Chlorhexidine is one of the most frequently used antiseptics. Having both bacteriostatic and bactericidal activities, chlorhexidine is used as a skin antiseptic before surgery, for urethral catheterization as a lubricant gel, and as a coating in central venous catheters.[116] It is also an ingredient in toothpaste, mouthwashes, and mouth rinses. Sensitization is most commonly associated with application to mucous membranes.[116] When applied to the skin as a hand-washing solution, low sensitization rates are attributed to poor transdermal absorption of chlorhexidine. Most allergic reactions are confined to the skin and manifest as urticaria with itching or contact dermatitis. However, anaphylaxis has been reported perioperatively after skin antisepsis, following insertion of a chlorhexidine-coated central venous catheter, and during tooth brushing. Both skin prick and intradermal testing have been used to identify high-risk patients before surgery. In a case series of six severe, immediate reactions to chlorhexidine that occurred during surgery, the onset of reactivity was within 10 to 20 minutes of chlorhexidine exposure.[115] When assessed 6 weeks after surgery, five of the six patients had self-reported prior histories of reactivity to chlorhexidine and four of the six demonstrated reactivity to skin prick testing.[115] The results of skin testing, the rapid onset and the increased intensity of reactivity observed upon reexposure to chlorhexidine support an IgE-mediated mechanism. Based on the widespread use of this antiseptic, chlorhexidine should be considered as a potential cause of any unexplained allergy. Once recognized as sensitized, patients must be educated to avoid subsequent exposures in both healthcare settings (eg, handwashing solutions and skin antiseptics) and in the private home (eg, personal hygiene products containing chlorhexidine).

TREATMENT

⑨ The basic principles for the management of allergic reactions to drugs or biologic agents include (a) discontinuation of the medication or offending agent when possible; (b) treatment of the adverse clinical signs and symptoms; and (c) substitution, if necessary, of another agent.

Anaphylaxis

Anaphylaxis requires prompt treatment to minimize the risk of serious morbidity or death. On presentation, attention should be given first to stopping the likely offending agent, if possible, and restoring respiratory and cardiovascular function. In 2020, the Joint Task Force on Practice Parameters for

Allergy and Immunology updated the treatment guidelines for anaphylaxis (see Table e108-2).[19] Epinephrine remains the drug of first choice, although it is underused and often dosed suboptimally for this indication.[117] Underuse and delays in its administration have been associated with poor outcomes. Epinephrine should be administered as a primary treatment to counteract bronchoconstriction and peripheral vasodilation leading to hypotension.[19,117] At recommended doses, epinephrine also enhances coronary blood flow. The recommended administration technique is intramuscularly in the lateral aspect of the thigh.[19,118] If blood pressure is not restored by epinephrine, crystalloid IV fluids should be administered to restore intravascular volume. Typically, 1 L of 0.9% sodium chloride is administered over 5 to 10 minutes. This can be repeated if the patient is still volume depleted. A maintenance IV fluid then is initiated. IV fluids should be given early in the treatment course in an attempt to prevent shock. An immediate priority is to establish and maintain an airway with endotracheal intubation if necessary. When a patient with anaphylaxis is hypotensive, vasopressors may be needed in addition to crystalloids. Norepinephrine is the vasoconstrictor agent of choice for treatment of anaphylactic shock and the use of a continuous IV infusion of epinephrine has also been described.[19,119] Patients in shock should remain supine.[19]

TABLE e108-2

Treatment of Anaphylaxis

- Remove the inciting allergen, if possible.
- Assess airway, breathing, circulation, and orientation. Support the airway.
- Cardiopulmonary resuscitation: Start chest compressions (100/min) if cardiovascular arrest occurs at any time.
- Administer epinephrine 1:1,000 (in a dose of 0.01 mg/kg to a maximum of 0.5 mg in adults and 0.3 mg in children) IM in the lateral aspect of the thigh.
- Place the patient in a recumbent position.
- Administer oxygen 8-10 L/min through facemask or up to 100% oxygen as needed; monitor by pulse oximetry, if available.
- Repeat IM epinephrine every 5-15 minutes for up to three injections if the patient is not responding.
- Establish IV line for venous access. Keep line open with 0.9% saline solution. For hypotension or failure to respond to epinephrine, administer 1-2 L at a rate of 5-10 mL/kg in the first 5-10 minutes. Children should receive up to 30 mL/kg in the first hour.
- Consider nebulized albuterol 2.5-5 mg in 3 mL of saline for lower airway obstruction; repeat as necessary.
- In cases of refractory bronchospasm or hypotension not responding to epinephrine because a β-adrenergic blocker is complicating management, glucagon 1-5 mg IV (20-30 µg/kg; maximum, 1 mg in children) given IV over 5 minutes.
- Give norepinephrine or epinephrine by continuous IV infusion for patients with inadequate response to IM epinephrine and IV saline. For epinephrine, add 1 mg (1 mL of 1:1,000) to 1,000 mL of 0.9% saline solution; start infusion at 2 µg/min and increase up to 10 µg/min based on blood pressure, heart rate, and cardiac function.
- Consider intraosseous access for either adults or children if attempts at IV access are unsuccessful.
- Consider diphenhydramine (adults 25-50 mg; children 1 mg/kg, up to 50 mg) IM or by slow IV infusion.
- Consider ranitidine 50 mg in adults and 12.5-50 mg (1 mg/kg) in children. The dose may be diluted in 5% dextrose in water to a volume of 20 mL and injected over 5 minutes.
- Consider methylprednisolone 1-2 mg/kg/dose up to 125 mg (or an equivalent steroid) to reduce the risk of recurring or protracted anaphylaxis. Prednisone 20 mg orally can be given in mild cases. These doses can be repeated every 6 hours as required.

IM, intramuscular.

Adapted from Shaker MS, Wallace DV, Golden DB, et al. Anaphylaxis: A 2020 practice parameter update, systematic review, and grading of recommendations, assessment, development and evaluation (GRADE) analysis. J Allergy Clin Immunol. 2020;145:1082-1123.

Other agents may be required for the treatment of anaphylactic reactions. Corticosteroids (hydrocortisone sodium succinate IV) should never be given in place of or before epinephrine.[19] Their onset of action is delayed, and their role is to reduce the risk of late-phase "biphasic" reactions. In patients treated chronically with β-blockers, glucagon should be considered because it has inotropic and chronotropic effects that do not rely on β-receptor responsiveness.[19] Histamine (H_1)–receptor blockers (eg, diphenhydramine) can be administered to reduce some of the symptoms associated with anaphylaxis, but these agents are not effective as primary therapy. The combination of diphenhydramine and an H_2-receptor blocker (eg, ranitidine) is superior to diphenhydramine alone in the treatment of cutaneous manifestations of anaphylaxis.[19] Intraosseous access should be considered for adult and pediatric patients in whom attempts at IV access are unsuccessful.[19,119]

Following the treatment of anaphylaxis, patients should be assessed for possible recurrence. Patients who may reencounter the allergic trigger (eg, peanuts, shellfish, and medications) should be prescribed auto-injectable epinephrine.[120] Adults should receive the 0.3 mg dose and children should receive the auto-injector that delivers 0.15 mg per dose.[120] Patients should be instructed to carry two auto-injectors at all times.[19] Optimal dosing has not been described for obese patients. Both adequate needle length for intramuscular delivery of the drug and weight-based dosing are concerns in the obese population.[120] Patient education is crucial to prevent fatalities due to underuse and incorrect administration of epinephrine.

Delayed Allergic Reactions

Except for anaphylaxis, the treatment of other drug allergies or DHRs is less defined and standardized. Questions most often arise regarding the preferred treatment of SCARs. After the offending agent is discontinued, treatment of SJS/TEN is directed at supportive care including wound care, nutritional support, fluid and electrolyte balance, temperature regulation, pain management and the prevention of infectious complications.[15] Affected patients, particularly those with extensive epidermal involvement, should be managed in a burn center or ICU. Wounds should be treated similar to that of burn injuries, but topical use of silver sulfadiazine is typically avoided because of a high risk of cross-reactivity with sulfamethoxazole, a major offender in SJS/TEN. To prevent blindness or conjunctival scarring, ocular therapy involves the use of antiseptics, lubricants, antibiotics, and steroid eye drops or ointments. The use of systemic steroids remains controversial. In a systematic review of published studies, only one of six retrospective cohort studies demonstrated a significant impact of steroids on mortality.[121] The appropriate dose, time of initiation of therapy, and duration of steroid therapy are not known. Additional therapies used in the treatment of SJS/TEN include intravenous immunoglobulin (IVIG) and cyclosporine. A proposed mechanism of IVIG is inhibition of dermal cell apoptosis triggered by the Fas-FasL pathway. Both low-dose (0.2-0.5 g/kg) and high-dose (2-3 g/kg) IVIG regimens have been described with most studies supporting the use of mean total IVIG doses not less than 2 g/kg.[122] Cyclosporine (3-5 mg/kg/day for 7 days) was associated with a greater mortality benefit as compared to IVIG (total of 1 g/kg for 3 days).[123] Similar to corticosteroids, treatment protocols of these agents substantially differ, and the optimal doses, time of initiation, and duration of therapy are yet to be determined.

Antibiotic Allergy Evaluation

⑩ Patients presenting with a subjective allergy, especially to antibiotics, should be evaluated for specifics of the reaction and offending agent that likely caused the response. Identification of patients at high risk for drug allergy requires careful history taking with attention to the specific agent to which the patient reacted, a complete description of the reaction, and the time since last exposure to the culprit drug. The importance of an accurate and complete history cannot be overstated. The end goal should be to de-label patients who are not truly allergic. Options that are available to the patient include skin testing, desensitization, graded dose challenge, or rechallenge.[124,125] Patients with negative tests should be educated on the importance of not continuing to identify as having an allergy.

Skin Testing

Skin testing followed by an optional oral challenge can be used to assess reactive risk to some drugs, but many of the testing procedures have not been validated and are not available for most culprit drugs. PST is the only available commercial product in the United States used to determine true allergenicity. PST should not be performed in patients with a history of severe mucocutaneous reactions (eg, SJS, TEN) or other nonimmediate reactions (eg, serum sickness, vasculitis, and hepatitis).

⑩ PST can reduce the uncertainty of penicillin sensitivity and should be performed in all patients who have a history of an immediate allergy and require treatment with a β-lactam antibiotic. PST in advance of the need for penicillin treatment in patients with a history of penicillin allergy does not induce sensitization.[126] Testing for the major penicillin determinant is accomplished with penicilloyl-polylysine (PPL; Pre-Pen), a product reintroduced in the United States in 2009. Ideally, skin testing should be performed with both the major and minor determinants. Of the minor determinants, only penicillin G is commercially available in the United States, and it should be used at a concentration of 10,000 units/mL with PPL in skin testing.[36,127] If left in solution to "age," penicillin G will not spontaneously degrade to form the other minor determinants, penilloate and penicilloate.[3] Similar reaction rates to oral penicillin challenges have been shown in patients with skin test negativity to PPL plus penicillin G compared with those with skin test negativity to the full set of major and minor determinants.[36,38] Skin testing with the major and minor determinants facilitates the safe use of penicillin in up to 90% of patients with a history of immediate penicillin allergy.[36] In patients who report a history of penicillin allergy but are skin test negative, the risk of resensitization (eg, conversion to a positive skin test result) after a course of penicillin ranges from 1% to 28%.[128] The procedure for performing PST is described in Table e108-3. In Europe, skin testing can be accomplished with a kit containing both the major and minor determinant mixture (Diater Labs, Madrid, Spain).[75]

TABLE e108-3

Procedure for Performing Penicillin Skin Testing

Step 1: Prick Test

This will be performed first on the patient, before proceeding to intradermal testing.

1. Clean the volar surface of either forearm with an alcohol swab.
2. Using an ink pen, draw 3 vertical lines approximately 1 in. (2.5 cm) apart on the designated testing site of the arm.
3. Draw up 0.1 mL of the four solutions (Pre-pen, diluted Penicillin G, histamine positive control, and saline negative control) in four separate allergy syringes.
4. Apply a small drop of each solution to the separate pre-marked sites on the testing arm.
5. The histamine test site should be the most distal site from the elbow, followed up the arm by saline, Pre-Pen, and Pen G
6. Puncture the epidermis using a twisting motion with a sterile 22-28 gauge needle at each drop site. Do not draw blood. Little pressure is required.
7. Read the test in 15-20 minutes: (document test results below)

   Test is **negative:** change in diameter of the wheal is **less than** 3 mm than that observed with the negative control. **Proceed to intradermal test.**

   Test is **positive:** change in diameter of the wheal is **greater than** 3 mm than that observed with the negative control. As soon as a positive response is observed, the solution should be wiped off the skin. **Do not proceed to intradermal test.**

   The positive control (histamine skin test) should be positive to ensure the results are not falsely negative.

   The negative control (saline skin test) should be negative. If a wheal >2-3 mm develops after 20 minutes, repeat prick skin test. Upon retesting, if control still creates a wheal >2-3 mm after 20 minutes, discontinue test and notify the appropriate clinician (eg, ID physician, ID stewardship pharmacist, Allergist).

Step 2: Intradermal Test

Only conduct this test if the patient produced a negative result with the prick test in step 1.

1. Select five sites on the volar surface on the forearm. These sites should be on the opposite arm from the prick test if possible.
2. Using a 26-30 gauge, short bevel needle, intradermally inject 0.02 mL of Pre-Pen solution **twice** (separate at least 2 cm apart). Mark the margins of the initial blebs with an ink pen.
3. Using separate needles and syringes, intradermally inject diluted Pen G (0.02 mL = 200 units of penicillin) **twice** (separate at least 2 cm apart) and 0.02 mL of saline (separate at least 5 cm apart from other sites).
4. Read in 20 minutes: (document test results below)

   Test is **negative**: there is no increase in the original bleb and no greater reaction than the negative control site.

   Test is **positive**: bleb or wheal increases >2 mm from its original size or is >2 mm larger than the negative control. **Patient is NOT to receive penicillin.**

Step 3: (Optional) Oral Penicillin Challenge

1. If deemed necessary by ordering clinician

   Oral penicillin (eg, amoxicillin 250 mg) challenge or graded challenge of target drug in a monitored setting for 30-45 minutes.

Data from Reference [134].

A negative PST result indicates that the risk of life-threatening immediate reactions is extremely low with the administration of penicillin or other β-lactams. Such patients are candidates for treatment with full therapeutic doses of a penicillin or a related β-lactam antibiotic. Certain patients (eg, those with dermatographism, taking H_1 antihistamines) may be unsuitable for PST because a false-positive or false-negative test may result. To prevent interference with skin testing, drugs with antihistaminic properties should be discontinued 48 to 72 hours before skin testing, especially H_1 antagonists. Penicillin is the only drug for which the predictive value of skin testing has been well established. Although the negative predictive value is high, PST with the major and minor determinants does not identify patients who are at risk for unique side-chain–mediated reactions to β-lactams (eg, third-generation cephalosporins, piperacillin). Dilute concentrations of amoxicillin and piperacillin have been used to skin test for side chain–mediated reactions.[44–46] The value of skin testing to predict the risk of allergic reactions to other antibiotics (eg, sulfonamides, tetracyclines, and fluoroquinolones) is largely unknown.[127]

Skin testing is also used to identify patients at risk for hypersensitivity reactions to carboplatin. The negative predictive value of intradermal skin testing with carboplatin is 98% to 99% in patients who have received several treatment courses.[72]

Temporary Induction of Drug Tolerance and Desensitization

⑪ For some patients with a history of an immediate reaction to a drug, no reasonable alternatives exist, and the inciting drug or a related compound may be necessary for treatment of an underlying condition (eg, neurosyphilis requiring penicillin). In this situation, the temporary induction of drug tolerance is indicated. In the past, the term “desensitization” was used to describe the procedure of temporarily acquiring drug tolerance, whether the underlying mechanism of intolerance was immunologically mediated or not. Experts in drug allergy recommend that the phrase “induction of drug tolerance” be used in place of “desensitization” to globally describe procedures used to modify a patient’s response to a drug and temporarily allow safe drug therapy.[14] Induction of drug tolerance can involve a variety of drug mechanisms, including IgE-mediated immune mechanisms, non-IgE mechanisms, pharmacologic mechanisms, and undefined mechanisms (see Table e108-4).[3] Regardless of the underlying mechanism, all procedures used to induce drug tolerance involve a stepwise process of incremental dosing of the inciting drug or a related compound. Desensitization, a method to induce drug tolerance, specifically refers to the process in which mast cells are rendered less responsive to degranulation. This term should be used when the underlying mechanism of drug intolerance is believed to be IgE mediated (eg, anaphylaxis to penicillin).[3] Immediate reactions most amenable to desensitization include dermatologic (eg, flushing, pruritus, urticaria, and angioedema), upper and lower respiratory tract (eg, sneezing, dyspnea, and wheezing), gastrointestinal (eg, abdominal pain, nausea and vomiting), and cardiovascular (eg, hypotension).[75] Procedures to induce drug tolerance should not be used in patients with a history of severe non-IgE reactions to a drug such as DRESS, SJS, TEN, exfoliative dermatitis, hemolytic anemia, or hepatitis.

TABLE e108-4

Characteristics of Drug Tolerance Protocols

Underlying Mechanism	Initial Dose	Duration of Protocol	Potential Outcome of Process	Example
Immunologic IgE (desensitization)	Micrograms	Hours	Desensitization; renders mast cells less responsive to degranulation	Anaphylaxis to β-Lactam antibiotics; taxanes
Immunologic non-IgE	Milligrams	Hours to days (eg, 6 hours-10 days)	Not known	Delayed cutaneous reactions to trimethoprim–sulfamethoxazole
Pharmacologic	Milligrams	Hours to days (eg, 2 hours-5 days)	Cautious induction of a reaction followed by a shift in a metabolic process	NSAID-exacerbated respiratory disease
Undefined	Micrograms to milligrams	Prolonged; days to weeks	Not known	Isolated cutaneous reactions to allopurinol

Adapted from Solensky R, Khan DA. Drug allergy: An updated Practice Parameter. Ann Allergy Clin Immunol. 2010;105:259-273.

All procedures to induce drug tolerance should be performed by a physician experienced in the risks and management of severe allergic reactions in a monitored setting with resuscitation equipment available. The potential risks and benefits should be discussed with the patient. The procedures differ in starting dose, number of steps in the dosing process, and frequency of drug dosing. The specific procedure should be chosen based on an evaluation of the patient's history of the reaction with consideration to the specific inciting drug and the suspected underlying mechanism of drug intolerance (eg, IgE mechanism vs non-IgE mechanism vs pharmacologic mechanism). The starting dose for a desensitization procedure is typically 1/1,000th of the final therapeutic dose, and the procedure can be completed within 4 to 12 hours.[3,38] A rapid 12-step desensitization protocol has been described and tested in patients with both IgE- and non-IgE-mediated reactions to antibiotics, platinum-containing chemotherapeutic agents, taxane chemotherapy agents, and monoclonal antibodies.[73,75] The 12-step method starts with a 1:1,000 dilution of the final dose of the inciting drug. Incrementally increased doses are administered every 15 minutes with three 10-fold diluted solutions. This method has been tested in nearly 800 patients, including patients with cystic fibrosis and allergy to antibiotics.[75] In high-risk patients, desensitization is achieved with either a 16- or a 20-step protocol.[73,75]

In the case of penicillin or β-lactam allergy, desensitization should be performed with the specific β-lactam antibiotic that will be administered for treatment of the patient's infection. Before initiating the protocol, the patient should be stabilized and fluid, pulmonary, and cardiovascular function optimized. Premedications (antihistamines or corticosteroids) are not routinely advised because these agents may mask the early signs of acute reactions and do not reliably reduce the severity of acute reactions. About one-third of patients who have undergone desensitization to a penicillin will experience mild, transient allergic reactions either during the desensitization procedure or during penicillin therapy. Patients who can take oral medications should undergo desensitization with oral drugs. After the desensitization protocol is begun, it should not be interrupted except for severe reactions. Antihistamines or epinephrine can be administered to treat reactions. In addition, if the patient completes the desensitization regimen and then undergoes full-dose treatment, a lapse between doses of as few as 24 hours can allow for reemergence of sensitivity. A protocol for IV cephalosporin desensitization is listed in Table e108-5. Protocols for desensitization with other β-lactam antibiotics are also available.[129] The use of standardized antibiotic desensitization protocols is recommended to reduce the potential for medication error and better achieve the goals of antimicrobial stewardship.[130] It is important to note that unlike a negative PST, successful desensitization does not remove the allergy long-term from the medical record, but only allows for administration of the agent at that time.

TABLE e108-5

Induction of Drug Tolerance Protocol for IV Cephalosporin[a]

Preparation of Solutions			
	Volume of Diluents (eg, 0.9% NSS)	**Total to be Injected in Each Bottle**	**Final Concentration (mg/mL)**
Solution 1	250 mL	10 mg	0.04
Solution 2	250 mL	100 mg	0.4
Solution 3	250 mL	1,000 mg	4

Induction of Drug Tolerance Protocol					
Step	**Solution**	**Rate (mL/hr)**	**Time (min)**	**Administered Dose (mg)**	**Cumulative Dose (mg)**
1	1	2	15	0.02	0.02
2	1	5	15	0.05	0.07
3	1	10	15	0.1	0.17
4	1	20	15	0.2	0.37
5	2	5	15	0.5	0.87
6	2	10	15	1	1.87
7	2	20	15	2	3.87
8	2	40	15	4	7.87
9	3	10	15	10	17.87
10	3	20	15	20	37.87
11	3	40	15	40	77.87
12	3	75	184.4	922.13	1,000

NSS, normal saline solution.

[a] Full dose equals 1,000 mg. Total time was 349.4 minutes.

Adapted from Solensky R, Khan DA. Drug allergy: An updated Practice Parameter. Ann Allergy Clin Immunol. 2010;105:259-273.

Most reactions to trimethoprim–sulfamethoxazole in HIV-infected patients are non-IgE-mediated, and several protocols to induce tolerance to trimethoprim–sulfamethoxazole have been described. The preferred regimen is not known because the regimens have not been compared in controlled clinical trials. Tolerance to trimethoprim–sulfamethoxazole can be achieved within 2 days in most HIV-infected patients.[3] This can be accomplished with the following schedule of oral doses (milligrams of sulfamethoxazole–trimethoprim): day 1: 9 am, 4 and 0.8 mg; 11 am, 8 and 1.6 mg;

1 pm, 20 and 4 mg; 5 pm, 40 and 8 mg; day 2: 9 am, 80 and 16 mg; 3 pm, 160 and 32 mg; 9 pm, 200 and 40 mg; day 3: 9 am, 400 and 80 mg, and 400 and 80 mg daily thereafter. With this regimen, the failure rate was associated with higher relative and absolute $CD4^+$ cell counts. Other investigators have described a 6-hour oral regimen in HIV-infected patients and a more gradual 9-day oral regimen. Induction of drug tolerance should not be attempted in any patient with a history of an exfoliative reaction to trimethoprim–sulfamethoxazole.

Both rapid (over less than 4 hours) and traditional desensitization protocols are available for aspirin and clopidogrel.[103,131] Nearly all patients with aspirin-induced asthma and urticaria/angioedema can be effectively desensitized to subsequently receive aspirin for the treatment of cardiovascular disease.[102]

Graded Challenge and Rechallenge

Also known as test dosing, a graded drug challenge involves the cautious introduction of a drug when the risk of a reaction is deemed to be low. Unlike desensitization, a graded drug challenge does not modify the immune or nonimmune response to the drug.[3,120] A classic example is the slow introduction of a cephalosporin in a patient with a history of reacting to another cephalosporin with a dissimilar R1 side chain.[129] Graded challenge protocols have been described for the slow introduction of furosemide in a patient with heart failure and a history of sulfonamide allergy.[132,133] Challenge dosing is not recommended in patients with a history of a severe drug allergy (eg, anaphylaxis, SJS, and TEN). Premedications should not be used because they may mask signs of an early breakthrough allergic reaction. Compared with drug tolerance procedures, graded challenges involve higher starting doses and fewer steps in the dosing process. The starting dose is typically 1/10th to 1/100th of the final treatment dose, and the oral route of drug administration is preferred to limit the risk of a severe reaction.[129] If no reaction occurs to the initial dose, the dose may be increased in two- to five-fold increments and administered every 30 to 60 minutes until the full therapeutic dose is achieved.[46,129] There is no standard protocol for graded challenge dosing but two- and three-step protocols are described. Although the risk of breakthrough infections is low, graded challenges should be performed in monitored settings.

Low-risk individuals who have a remote allergy to penicillin or other antibiotics that is unlikely to be IgE-mediated can be safely challenged with a therapeutic dose to confirm tolerance.

CONCLUSION

The approach to the evaluation and management of drug allergy has evolved over the past several decades from prohibitive to proactive. The discovery of a drug allergy previously eliminated certain preferred pharmacotherapeutic options. More current evidence-based approaches based on an understanding of the immunologic mechanisms of drug allergy now allow the use of first-line medications in many patients. As a result, clinical and organizational outcomes improve when drug allergy optimization practices are incorporated into routine clinical care.

ABBREVIATIONS

ACE	angiotensin-converting enzyme
APC	antigen presenting cell
ARBs	angiotensin-receptor blockers
CI	confidence interval
CNS	central nervous system
COX	cyclooxygenase
CYP	cytochrome P-450

DHR	drug hypersensitivity reaction
DRESS	drug rash with eosinophilia and systemic symptoms
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
ICON	International CONsensus
IgE	immunoglobulin E
IVIG	intravenous immunoglobulin
LT	leukotriene
NSAID	nonsteroidal anti-inflammatory drug
OR	odds ratio
PAF	platelet-activating factor
PG	prostaglandin
PPD	purified protein derivative
PST	penicillin skin testing
SCAR	serious cutaneous adverse reaction
SJS	Stevens-Johnson syndrome
SLE	systemic lupus erythematosus
SSLD	serum sickness–like disease
TEN	toxic epidermal necrolysis

SELF-ASSESSMENT QUESTIONS

1. In a patient with a history of anaphylaxis to penicillin G, which of the following statements is correct?

   A. The risk of a cross-reaction to an antipseudomonal penicillin is low, averaging 10%.

   B. The risk of a cross-reaction to a first-generation cephalosporin is <7.5%.

   C. The risk of a cross-reaction to a third-generation cephalosporin is 5% to 7.5%.

   D. The risk of a cross-reaction to imipenem or meropenem is about 50%.

2. An anaphylactoid reaction differs from an anaphylactic reaction in which of the following ways?
    A. An anaphylactoid reaction does not involve an IgE-mediated mechanism.
    B. An anaphylactoid reaction only occurs on first exposure to a drug and does not recur on subsequent drug exposure.
    C. An anaphylactoid reaction does not cause bronchospasm.
    D. An anaphylactoid reaction is not responsive to treatment with epinephrine and/or corticosteroids.
3. Which of the following statements is false regarding reactions to aspirin?
    A. About 20% of patients with asthma are sensitive to aspirin.
    B. Patients who develop aspirin-induced asthma are generally sensitive to other COX-1 NSAIDs.
    C. Aspirin is believed to cause allergic-like reactions by blocking cyclooxygenase which facilitates the production of alternative arachidonic acid metabolites.
    D. Aspirin desensitization has not been shown to improve asthma scores and symptoms in aspirin-sensitive patients.
4. Which of the following statements is correct regarding the risk of hypersensitivity to the sulfonamide class of agents?
    A. The risk is less with the sulfonamide antibiotics as compared with the sulfonamide nonantibiotics (eg, thiazides, sulfonylureas).
    B. Cross-reactivity between the sulfonamide antibiotics and nonantibiotics is about 50%.
    C. Trimethoprim–sulfamethoxazole is considered the least allergenic sulfonamide agent.
    D. The risk of allergic or allergic-like reactions to sulfonamides is increased in HIV-infected patients and those with other immunocompromised states.
5. Which of the following statements is true regarding a type III (immune complex) allergic drug reaction?
    A. Occurs within 24 hours of initial drug exposure
    B. Involves complement activation in response to the antigen–antibody complex
    C. Typically manifests as an allergic blood disorder
    D. Is synonymous with a delayed hypersensitivity reaction
6. Which antibody is involved in a type I allergic drug reaction?
    A. IgE
    B. IgG
    C. IgM
    D. IgA
7. Which of the following is false regarding allergic or allergic-like reactions with radiocontrast agents?
    A. The risk is greater in women and patients with a history of atopy or asthma.
    B. An allergy to seafood predisposes to radiocontrast reactions.

C. Reactions to radiocontrast media can largely be prevented by appropriate screening mechanisms and pretreatment with prednisone and diphenhydramine.

D. Skin testing with different radiocontrast agents may help identify a product with a low reactive risk

8. Which of the following patients is an appropriate candidate for skin testing for penicillin allergy?

A. A patient with a history of Stevens-Johnson syndrome associated with piperacillin

B. A patient with a history of drug rash with eosinophilia and systemic symptoms (DRESS) associated with amoxicillin

C. A patient with a history of a diffuse maculopapular rash with ampicillin–sulbactam

D. A patient with a history of bronchospasm and urticaria with penicillin G

9. Is the following statement true or false? The low-osmolar (nonionic) radiocontrast agents have a greater frequency of allergic-like reactions compared with the high-osmolar agents.

A. True

B. False

10. The subtypes of type IV allergic drug reactions are differentiated based on which of the following features?

A. The type of responding antibody (eg, IgG, IgA, IgM, and IgE)

B. The presence or absence of pruritus as a manifestation of the reaction

C. The responding T cell (eg, T helper type I cell, T helper type II cell, and cytotoxic T cell)

D. The onset of the reaction (eg, less than 24 hours vs greater than 24 hours after drug exposure)

11. Which of the following statements reflects the primary differentiating feature between graded challenge dosing and desensitization?

A. Graded challenge allows for more rapid modification of the immune response and a faster time to desensitization.

B. Graded challenge is used when the risk of a severe reaction to a drug on reexposure is considered to be low.

C. Desensitization is effective in patients with a wider range of allergic reactions including severe skin reactions (eg, Stevens–Johnson syndrome, toxic epidermal necrolysis).

D. Graded challenge is only performed using oral doses of the offending allergenic drug.

12. A negative penicillin skin test is unable to predict if the patient will have side-chain–mediated reactions to beta-lactams.

A. True

B. False

13. Which of the following is the correct dose of epinephrine for anaphylactic reactions in an adult?

A. 0.01-0.03 mg

B. 0.3-0.5 mg

C. 0.5-1 mg

D. 1-2 mg

14. Which of the following allergic drug reactions may be IgM-mediated?

    A. Type I

    B. Type II

    C. Type III

    D. Type IV

15. In type I allergic reactions, allergens bind to which immune cells resulting in the release of inflammatory mediators?

    A. T cells

    B. Basophils

    C. Cytokines

    D. Eosinophils

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** The risk of cross-reaction to a first- and second-generation cephalosporin in a patient with a history of anaphylaxis to penicillin G is 7.5%. The rate drops to 1% for third- and fourth-generation cephalosporins.

2. **A.** Anaphylactoid reactions are non-IgE-mediated while anaphylactic reactions are IgE-mediated.

3. **D.** Aspirin desensitization can be effective for patients with aspirin-induced asthma and symptoms (urticaria, angioedema)—especially if they have a cardiac indication for asthma.

4. **D.** Adverse reactions to trimethoprim-sulfamethoxazole occur in about 50% to 80% of AIDS patients and 10% of other immunocompromised patients. A is incorrect as the risk of hypersensitivity is greater with sulfonamide antibiotics. B is incorrect as cross-reactivity between sulfonamide antibiotics and nonantibiotics is highly unlikely. C is incorrect as trimethoprim-sulfamethoxazole is considered the most allergenic sulfonamide agent.

5. **B.** Type III reactions are in response to antigen-antibody complexes in the blood that cause complement activation. A is incorrect because type III reactions are delayed and manifest >72 hours to weeks from exposure. C is incorrect as it manifests as vasculitis or serum sickness disorder. D is incorrect as type III is not the only delayed reaction type.

6. **A.** Type I reactions are IgE-mediated.

7. **B.** Seafood or iodine allergies do not predispose a patient to radiocontrast reactions.

8. **D.** Patients with a history of an IgE-mediated hypersensitivity reaction to a penicillin are appropriate candidates for penicillin skin testing. A and B are incorrect because skin testing should not be conducted in patients with severe non-IgE mediated reactions. C is incorrect as maculopapular rash is not an IgE-mediated reaction.

9. **B.** The low-osmolar agents cause fewer allergic-like reactions.

10. **C.** The subtypes of type IV allergic drug reactions are differentiated between the type of responding T cell and not the manifestation or timing of reaction—making choices B and D incorrect. Type IV reactions are not antibody mediated so answer A is incorrect.

11. **B.** Since graded challenge dosing does not modify the immune/nonimmune response to a drug, it is used when the risk of a severe reaction to a drug is low upon reexposure. A is incorrect as a graded challenge is slower than desensitization. C is incorrect as a graded challenge should not be used in patients with a history of a severe drug allergy. D is incorrect as drugs other than the offending allergenic drug may be used.

12. **A.** Patients may still be susceptible to unique side-chain mediated reactions.

13. **B.** The adult dose is 0.3 to 0.5 mg. Typically, the dose is 0.01 mg/kg up to 0.3 mg for children and 0.5 mg for adults.

14. **C.** Type III reactions may be IgG- or IgM-mediated and are characterized by antigen-antibody complexes.

15. **B.** Allergens bind to IgE on basophils in type I reactions. A is incorrect as T cells are involved in Type IV reactions. C is incorrect as cytokines may be released following T cell activation in Type IV reactions. Eosinophils are seen in response to Type IVa reactions making D incorrect.

Chapter e116: Drug-Induced Ophthalmic Disorders

Rena Gosser

KEY CONCEPTS

KEY CONCEPTS

① The eye is highly susceptible to drug toxicity due to its extensive vasculature.

② When ophthalmic disorders occur, all medications and biologic agents, irrespective of the route of administration, are potential causes.

③ It is difficult to fully quantify the incidence of drug-induced ophthalmic disorders due to the variety of causative factors and side-effect reporting behaviors of clinicians.

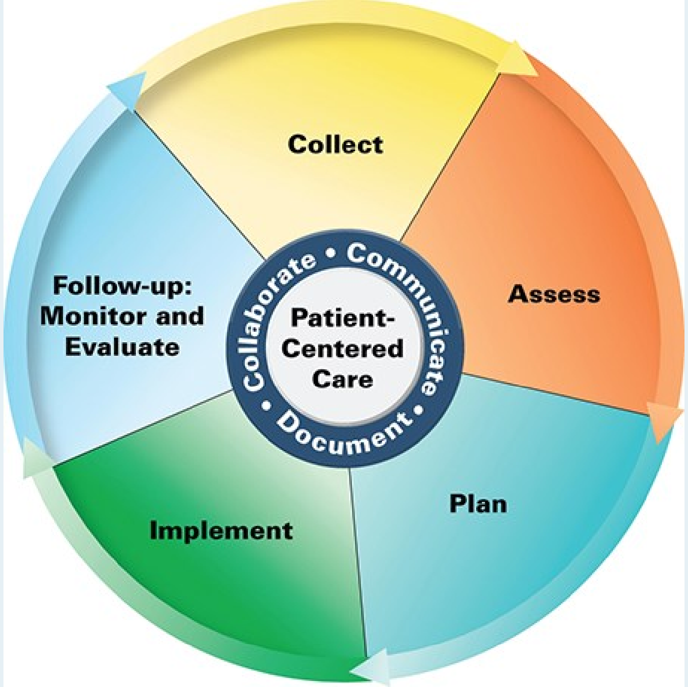
④ The most common drug-induced ophthalmic disorders include dry eye, cataract, intraoperative floppy iris syndrome, optic neuropathy, and retinopathy.

⑤ The severity of drug-induced ophthalmic disorders varies and depends on dose, pharmacokinetics, genetic predisposition, age, extremes of body weight, and/or duration of exposure.

⑥ Health professionals and patients should discuss potential drug-induced ophthalmic disorders to ensure awareness, prompt identification, management, and treatment.

PATIENT CARE PROCESS

Patient Care Process for Drug-Induced Ophthalmic Disorders



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnancy status)
- Patient medical history (personal and family)
- Social history (eg, tobacco/ethanol use)
- Current or recently discontinued medications including prescription, over-the-counter (OTC) aspirin/NSAID use, herbal products, dietary supplements
- Objective data (eg, drug levels)

Assess

- Appearance of ophthalmic signs or symptoms
- Presence of predisposing conditions or risk factors
- Presence of physical occlusion of the eye or eyelid
- Presence of common provoking factors (eg, recent drug use, new medications, history of allergies)
- Potential causative agent
- Appropriateness for self-care (eg, red flags that would indicate referral or higher level of care)
- Ability/willingness to administer eye drops appropriately (eg, health literacy, age of patient)
- Ability/willingness to pay for OTC options not covered by insurance
- Ability/willingness to follow-up with the provider if symptoms do not improve

Plan

- Discontinuation of the offending agent, if applicable
- Pharmacologic and nonpharmacologic treatment regimen with medication(s), dose, route, frequency, and duration of treatment (see Table e116-4)
- Monitoring parameters including efficacy (eg, resolution/improvement in symptoms); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, medication administration technique)
- Self-monitoring for resolution of symptoms
- Referral to other providers when appropriate

Implement

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up labs (eg, drug levels) and/or ophthalmic examination

Follow-Up: Monitor and Evaluate

- Resolution of eye symptoms
- Drug level results, as appropriate
- Presence of adverse effects
- Patient adherence to treatment plan and scheduled care visits
- Schedule regular ophthalmic examinations
- Reevaluate as necessary

BEYOND THE BOOK

BEYOND THE BOOK

Watch the following videos available from the US National Library of Medicine MedlinePlus for a brief overview of the anatomy and function of the eye. These videos provide the necessary foundation and will assist in understanding the mechanisms of drug-induced ophthalmic disorders.

Blinking: https://medlineplus.gov/ency/anatomyvideos/000010.htm (1:01)

INTRODUCTION

① The eye is an important, complex organ of the nervous system. It is composed of specialized tissues and complex structures that collectively contribute to the body's ability to visually process the environment (Fig. e116-1).[1–3] The sequence for normal, functioning eyes begins with the eyelid, which opens to allow exposure to light, bathes the eye with tear film, and helps remove waste. The eye receives light through the cornea, a clear tissue at the front of the eye. The light then proceeds through the aqueous humor and enters the pupil. The light continues through the pupil, which regulates the amount of light entering the eye to the lens. The lens changes thickness and shape to bend the received light and send it through the vitreous humor to the retina at the back of the eye.[1–3] The retina then transforms the light into electrical impulses, which travel through the optic nerve to the brain. The brain then translates these impulses into the image that is seen. The function of each structure of the eye is summarized in Table e116-1.[2,3]

TABLE e116-1

Summary of the Structures and Function of the Eye

Part of Eye	Function
Aqueous humor	Fills the anterior chamber of the eye; maintains eye pressure
Conjunctiva	Clear membrane that covers the surface of the eye
Eyelid	Protects the eye, keeps foreign bodies from contacting the eye, and keeps the eye moist by spreading tear film
Iris	Colored portion of the eye Dilates or constricts the pupil
Cornea	Clear tissue that focuses light on the retina
Lacrimal gland	Produces tears
Lens	Focuses light and changes shape to focus on objects
Macula	Functional center of the retina Responsible for fine detail, central and color vision
Meibomian gland	Produces the oil layer of the tear film
Optic nerve	Receives and transmits electrical information from the retina to the brain for processing
Pupil	Dilates or constricts to allow varying amounts of light to reach the retina
Retina	Tissue in the back of the eye that contains photoreceptors responsible for color, night, and detailed vision
Sclera	White membrane that covers the surface of the eye
Tear duct	Canal that drains tears from the eye
Tear film	Composed of three layers (mucus, aqueous, and oil) to lubricate the eye
Vitreous humor	Fills most of the eye; maintains shape of eye and holds retina in place

Data from References 2,3.

① ② Disruption at any structure or step in the process can lead to dysfunction of the eye. This can result from many factors. Exposure to toxic substances, including medications, is one such cause of dysfunction. The combination of a rich blood supply and extensive vasculature allows for ocular exposure to systemically administered medication. The blood-aqueous and blood-retinal barriers are capable of keeping most compounds away from the eye; however, some medications are able to bypass the junctions within cells and reach the eye.[4] The eye is the second most common organ to display drug toxicities, with the liver considered most common.[5]

③ It is difficult to accurately quantify the incidence of drug-induced ophthalmic disorders overall.[4,6] All medications have the potential to induce side effects, irrespective of the mode of administration. Side effects may range from mild to severe and can affect any area of the eye. Many but not all drug-induced ophthalmic disorders are well documented in the literature; lack of clinician or patient reports is a limiting factor. Despite any potential gaps in the literature, it is important to establish causality between an ophthalmic side effect and medication use. A popular tool used by clinicians to establish the likelihood of causality is the adverse drug reaction probability scale, commonly known as the Naranjo scale.[7] The Naranjo scale is composed of scored questions the clinician should use to assess an adverse drug reaction. Categories of definite, probable, possible, and doubtful are assigned based on the score.[7]

This chapter will discuss drug-induced ophthalmic disorders seen with commonly prescribed medications in clinical practice. A review of drug-induced glaucoma will not be covered in this chapter, as it is discussed in Chapter 114, “Glaucoma.”

DRUG-INDUCED OPHTHALMIC REACTIONS

Dry Eye Disease

④ Dry eye disease (DED), also known as dry eye syndrome or keratoconjunctivitis sicca, is a common ophthalmic disorder that affects the quality of life for millions of people around the world.[6,8] In addition to the discussion of DED in this chapter, nonprescription therapies for the condition are detailed in Chapter e11, “Minor Ophthalmic Disorders (Conjunctivitis, Xerosis, Corneal Abrasions, Bacterial Keratitis).”

The prevalence of DED ranges from 5% to 50% due to a lack of a standardized definition and consistent diagnostic criteria.[6] DED accounts for $3.8 billion annually in healthcare expenditures in the United States, with quality-of-life impact on approximately $55 billion.[9]

DED is defined by the Tear Film & Ocular Surface Society International Dry Eye Workshop II (TFOS DEWS II) Definition and Classification Subcommittee as follows: “Dry eye is a multifactorial disease of the ocular surface characterized by a loss of homeostasis of the tear film, and accompanied by ocular symptoms, in which tear film instability and hyperosmolarity, ocular surface inflammation and damage, and neurosensory abnormalities play etiological roles.”[6]

This definition classifies DED as a condition with multiple contributing factors. The eye depends on a healthy tear film composed of mucus, aqueous, and mucin to maintain lubrication, provide nutrients, and remove waste.[2,3,10] DED can occur when any aspect of the tear film is compromised. This may be due to evaporation of the tear film, an imbalance in tear film composition, or decreased production of tears.[6,8,9] This pathophysiologic mechanism leads to patient reports of light sensitivity, pain, blurry vision, and a feeling of grittiness in the eye.[8,9]

DED is common in the older population because of polypharmacy and age-related changes. It is also common in women due to sex hormone effects on meibomian gland function and tear secretion.[6,9,10] Other risk factors for DED include anatomic disorders (floppy eyelid syndrome), autoimmune diseases (rheumatoid arthritis, Sjogren’s disease), diabetes, graft versus host disease, meibomian gland dysfunction, neural dysfunction (neuropathic pain), low sex hormone levels, prolonged computer screen time, systemic lupus erythematosus, and medications.[8,9]

Numerous systemic and topical medications can cause DED. These include alpha-1 antagonists, alpha-2 agonists, anticholinergics, anticonvulsants, antihistamines, antimalarials, antineoplastics, antipsychotics, anxiolytics, beta-agonists and antagonists, bisphosphonates, cannabinoids, systemic and topical decongestants, diuretics, retinoids, oral contraceptives, and tricyclic antidepressants.[8–12] Preservatives present in topical ophthalmic products, such as benzalkonium chloride, may cause DED by disrupting tear film homeostasis and causing inflammation.[8] A thorough patient history and examination should be collected to determine the risk factors present and the likely type of tear film issue at hand.

Several strategies are used to treat DED. Interventions aim to increase liquid on the ocular surface, decrease the amount of evaporation of eye fluids, and restore balance to tear film components.[6,8,13] Many of these medications must be used chronically; their benefits are viewed as outweighing any risks of long-term therapy. Agents include topical lubricants, anti-inflammatory ophthalmic drops such as 0.05% cyclosporine, and lymphocyte function-associated antigen 1 (LFA-1) antagonists.

Additionally, discontinuation of the causative agent, if possible, or switching to preservative-free ophthalmic drops and products can help alleviate DED symptoms. A summary of common causative agents and treatment options is available in Table e116-2.

TABLE e116-2

Strategies to Prevent Drug-Induced Ophthalmic Disorders

Educate patients on the signs and symptoms of common ophthalmic side effects related to prescribed medication.
Schedule regular ophthalmic examinations.
Use nonpharmacologic management when appropriate.
Prescribe prophylactic medication therapy when appropriate.
Avoid exceeding recommended daily dose, cumulative lifetime doses, or duration of therapy.
Assess for predisposing conditions or risk factors prior to use of medication.
Monitor drug levels as appropriate.
Stress importance of adherence to scheduled follow-up visits and monitoring.
Encourage communication of any new or discontinued prescription, natural medicine, or OTC products.

Data from References [4,5,14,16].

Punctal occlusion, a procedure in which the puncta—the small openings in the corner of the eye—are blocked, can benefit those with DED by decreasing tear drainage when other options have failed.[6] This provides the eye with tear availability to continually bathe the eye and decrease symptoms of DED.[6,10] If left untreated, severe DED may lead to corneal ulcers (Fig. e116-2), vascularization, and permanent vision impairment.[14]

Cataracts

④ Drug-induced cataracts may occur with the use of corticosteroids, phenothiazines, alkylating agents, and statins.[5,15] Patients presenting with cloudiness in specific parts of the lens can provide clues as to the route of administration of the causative agent.[5] Table e116-3 summarizes the location of lens changes observed by route of administration for medication classes known to cause cataracts. In general, systemically administered drugs cause changes along the equator of the lens, while topically administered drugs cause central anterior lens changes. Posterior subscapular and cortical changes may also occur irrespective of the route of administration.[5]

TABLE e116-3

Location of Lens Changes Observed by Route of Administration for Common Causative Agents that Induce Cataracts

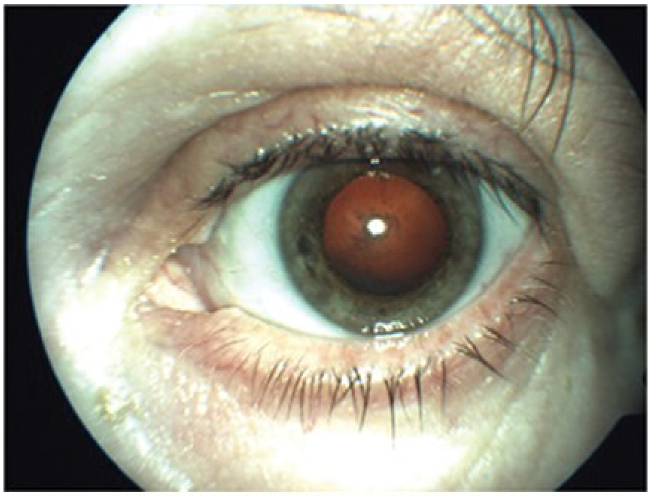
Route of Administration	Lens Change Location	Causative Medication
Systemic	Equator	Glucocorticoids
Topical	Central anterior	- Phenothiazines - Glucocorticoids
Mixed	Posterior subscapular	Alkylating agents (busulfan)
		Glucocorticoids
	Cortical (edges)	Statins
		Glucocorticoids

Data from References [5,14-16].

Corticosteroids may cause cataracts on any portion of the lens when used for an extended period of time (Fig. e116-3).[5,14] The incidence of cataract formation secondary to corticosteroid therapy is 22% to 58%.[14] Risk factors for adverse effects of corticosteroid therapy include young age, condition of the skin, extent of disease, location on the body, dose and duration of therapy, and use of occlusive dressings.[14] Topical application of corticosteroids to distal areas of the body, and in limited doses, has indicated minimal risk of cataract formation.[14] Discontinuation of corticosteroid therapy does not reverse the cataract.[5,14]

FIGURE e116-3

Steroid-induced cataract. (*Reproduced, with permission, from* Turno-Krecicka A, Grzybowski A, Misiuk-Hojło M, et al. Ocular changes induced by drugs commonly used in dermatology. *Clin Dermatol. 2016;34(2):129-137.*)



Source: Joseph T. DiPiro, Gary C. Yee, L. Michael Posey, Stuart T. Haines, Thomas D. Nolin, Vicki L. Ellingrod: *DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e*
Copyright © McGraw Hill. All rights reserved.

Phenothiazines, specifically chlorpromazine and thioridazine, cause cataract formation in a dose- and duration-dependent manner.[5] Fine granules that are white to brown in color form and accumulate in the anterior cortex over time, forming a cataract. Ophthalmic side effects are rare at standard thioridazine doses less than 800 mg/day.[5,16]

Alkylating agents, such as busulfan, cause a posterior subscapular cataract by interfering with the production of nucleic acid during mitosis.[5]

Statins are associated with an increased risk of cataracts, although for quite some time statin therapy was associated with a protective effect.[15,17,18] Clinicians must weigh the benefits and risks of statins in all cases prior to initiation of therapy.

In most cases, drug-induced cataracts remain relatively stable and will not reverse once formed, irrespective of the type of causative agent exposure. Surgical removal of the lens may be necessary to restore vision.[5,14]

Intraoperative Floppy Iris Syndrome

④ Intraoperative Floppy Iris Syndrome (IFIS) occurs in approximately 0.5% to 3.7% of patients undergoing cataract surgery worldwide, with a rate of approximately 2% in the United States.[19,20] It is characterized by presentation of one or more intraoperative events: floppiness and billowing of the iris, progressive intraoperative constriction of the pupil despite pharmacologic intervention to maintain dilatation, and prolapse of the iris through the surgical wound(s).[19] IFIS complicates the surgical procedure and may lead to endophthalmitis, pupil deformity, retinal detachment, and vitreous loss.[19–22]

The use of alpha-1 antagonists (tamsulosin, silodosin, alfuzosin, doxazosin, terazosin, and prazosin) is a major risk factor for development of IFIS.[23] IFIS is most commonly seen in men; however, women prescribed alpha-1 antagonist therapy for urinary stone passage, hypertension, or chronic urinary retention have also experienced IFIS.[20] Patients taking tamsulosin are 30 times more likely to experience IFIS, with a rate of approximately 60% to 89% in those undergoing cataract surgery.[23,24] Tamsulosin is highly selective for alpha-1_A receptors located in the bladder neck, prostate, and urethra. These receptors are also present in the smooth muscle of the iris. Binding of tamsulosin to these receptors inhibits dilatation and may lead to

IFIS. Discontinuing alpha-1 antagonist therapy prior to cataract surgery does not decrease the risk of IFIS.[20,24,25] Patients with a prior history of alpha-1 antagonist use are still at risk for IFIS, attributed to atrophy of the dilator muscle of the iris due to disuse.[26,27]

IFIS has also developed in patients with hypertension or those receiving therapy with other medications (finasteride, duloxetine, donepezil, quetiapine, and benzodiazepines).[23,28–33] Additional studies are needed to determine if the risk associated with hypertension is due to medication use or a disease process.[23,24] It remains unclear if the use of these medications represents an actual causative risk factor in the development of IFIS. More research is necessary to fully elucidate the iris smooth muscle relaxation activity of these agents.[23,28–31]

IFIS may be avoided by conducting a complete preoperative screening of a patient's medication regimen prior to cataract surgery. Intracameral administration of preservative-free epinephrine or phenylephrine at the beginning of surgery helps reduce IFIS and dilates the pupil.[20,28] Use of ophthalmic viscosurgical devices (OVDs), iris retractors, and pupil expanders are additional techniques that may be employed in conjunction with intracameral epinephrine or phenylephrine. Mechanical pupil stretching and partial sphincterotomy are not useful and may exacerbate IFIS.[20]

Optic Neuropathy

④ Drug-induced optic neuropathy (DION) is a subset of toxic optic neuropathy (TON), a disorder in which the optic nerve degenerates due to toxic exposure to medication therapy. Mitochondrial injury, blood flow disruption, and free radical exposure are possible pathophysiologic mechanisms leading to this condition.[5,34] DION is characterized by bilateral vision loss, decreased visual acuity, decreased color vision, and afferent pupillary defect.[5,34] Symptoms occur slowly over time and do not cause pain. TON is more common in developing countries due to exposure to toxins and drugs in the environment.[34] Epidemiological studies have not elucidated any age-, gender-, or race-related risk factors associated with TON or DION.[34]

DION has occurred most often with the use of amiodarone, ethambutol, linezolid, and PDE-5 inhibitors. Vision issues associated with these agents are dose and duration dependent. Discontinuation of the causative agent generally leads to reversal of symptoms.[5,14] It is critical to educate patients about this potential side effect of therapy to ensure prompt notification and discontinuation of therapy prior to development of permanent damage.

Amiodarone

Optic neuropathy is thought to occur due to accumulation of amiodarone in the axon, interfering with normal neural function and leading to vision loss.[5,16] The incidence of amiodarone-induced optic neuropathy is 1.79%.[16] Optic neuropathy occurs slowly over an average of 9 months due to the 160-day half-life of amiodarone, resulting in bilateral vision loss and optic disc edema.[4,16,34] Upon discontinuation of amiodarone, it may take months for vision loss to reverse. Ophthalmic examinations every 6 to 12 months are important, given the dose- and time-dependent nature of visual side effects related to amiodarone use.

Ethambutol

Optic neuropathy has been well documented in 6% of patients receiving ethambutol for treatment and prevention of tuberculosis.[34] The average time to development is 235 days of therapy.[5,16,34] Renal dysfunction may lead to diminished excretion of ethambutol and higher levels, lowering the time to development of optic neuropathy. Patients present with bilateral vision, loss peripheral constriction, and color vision loss.[5,16,34] Symptoms occur due to chelation of copper present in retinal cells. Chelation depletes copper available for mitochondrial activity, stunting the ability to acquire energy required for normal axonal transport.[5,16] If symptoms occur, the clinician should explore discontinuation of ethambutol as clinically appropriate.[5] Baseline eye examinations and ophthalmologic consultation is recommended to prevent vision loss and subsequent diminished quality of life.[34] Education on the risk of optic neuropathy and obtaining informed consent are also recommended as best practices for use of ethambutol.[16]

Linezolid

Linezolid-induced optic neuropathy is thought to be caused by mitochondrial injury.[5] Patients have generally experienced visual side effects after approximately 5 to 10 months of therapy, although a few cases have been reported in which loss of vision occurred after only 2 weeks of therapy.[5,34] Vision has improved after discontinuation of linezolid in most patients; some patients experience lasting visual acuity issues.[34] Patients on linezolid therapy need regular ophthalmic examinations.

Phosphodiesterase Type 5 Inhibitors

Phosphodiesterase type 5 (PDE-5) inhibitors (avanafil, sildenafil, tadalafil, and vardenafil) can cause DION, which manifests as blurriness, color discrimination deficits (particularly in the blue-green and blue-purple spectrum), and light sensitivity.[34] The color-related symptoms are thought to result from drug effects on phosphodiesterase type 6 (PDE-6) receptors present on the rods and cones of the eye.[35] These symptoms are dose-dependent and reverse upon discontinuation of the drug.[5]

Retinopathy

①④⑤Retinopathies occur due to medication exposure to the retina via the vasculature of the eye. Four main classes of drugs can cause retinopathies: aminoquinolines, antiestrogen agents (tamoxifen), phenothiazines, and retinoids. In patients taking these drugs, regular ophthalmic examinations are needed to monitor for early signs of retinal disorder, as late-stage retinopathy is virtually nonreversible.[5,36]

Aminoquinolines

Chloroquine and hydroxychloroquine use is associated with retinal issues. Risk for toxicity depends on total dose and duration of therapy. Patients receiving hydroxychloroquine doses greater than 5 mg/kg/day and chloroquine doses greater than 2.3 mg/kg/day are at greatest risk for retinopathy.[4,14,37] Aminoquinoline therapy for more than 5 years also increases the risk of toxicity.[14] Advanced age, extremes of body weight, liver disease, and renal disease are also risk factors for development of retinopathy due to hydroxychloroquine or chloroquine use.[5,16]

Aminoquinolines have a high affinity for melanin within the retinal pigment epithelium, allowing accumulation and prolonged effect. This ultimately contributes to toxicity seen with this class of medications. The retinal issue associated with aminoquinoline therapy is a maculopathy, in which the macula of the retina appears as a bull's eye or ring in most patients.[5,14] Ideally, conducting regular ophthalmic screenings, as described below, should make development of this bull's eye maculopathy a rarity.[37]

Patients typically present with complaints of color vision disturbance, central visual field defect, and loss of night vision.[4,14,16] To positively attribute maculopathy to hydroxychloroquine use, the maculopathy must be bilateral. It can be detected using visual field testing and Amsler grid.[5,16]

The American Academy of Ophthalmology recommends a dilated fundus exam and visual field test at baseline. A color vision test is also recommended but optional. Clinicians must conduct ongoing monitoring and regular ophthalmic examinations, with consideration for discontinuation of therapy if medically appropriate.[14] If patients continue use of the medication beyond 5 years, follow-up examinations are recommended every 12 months.[37] Once bull's eye maculopathy occurs, reversal of vision is not possible, leading to permanent vision loss.[5,14,16]

Phenothiazines

The mechanism of toxicity for phenothiazines is similar to that of aminoquinolines, whereas drug binds to melanin in the retinal pigment epithelium, causing degeneration of the retina.[5] At high doses, chlorpromazine retinal disorder causes conjunctival lesions, pigmentation of the eyelid, while high-dose thioridazine causes a rapid, severe retinopathy with a few weeks or months of use.[5] Patients present with diminished visual field and night vision loss.

Antiestrogen Agents

Tamoxifen is known to cause retinopathy and loss of color vision. Retinopathies manifest as retinal edema, hemorrhage, swelling of the optic disc, and yellow deposits around the macula.[5] As seen with other therapies, these effects depend on dose and duration and can occur within a few weeks after initiation of therapy.

Retinal effects are generally reversible when tamoxifen is discontinued. To prevent retinopathy associated with tamoxifen use, baseline ophthalmic examination with a color vision test and slit lamp biomicroscopy are recommended to be performed, with follow-up examinations completed every 2 years thereafter.

Retinoids

Patients on high-dose isotretinoin therapy are at high risk for night vision loss, blurry vision, dry eye, and blepharoconjunctivitis. The mechanism of toxicity is thought to occur due to binding site competition between retinoid acid and retinol.[5]

PREVENTION AND MONITORING

⑥ Before any medication is used in the eye, there must be an appropriate indication and the patient must understand potential risks and benefits. Education on signs and symptoms of untoward ophthalmic adverse effects should accompany a discussion with the patient about the use of the medication.

In patients using ophthalmic products, clinicians should encourage patients to receive routine ophthalmic examinations and follow-up as appropriate; this is especially important during treatment with a medication with potential adverse effects on these important organs.[4] Table e116-4 provides a list of general strategies that may be used to prevent drug-induced ophthalmic disorders.

TABLE e116-4

Common Drug-Induced Ophthalmic Disorders, Causative Agents, Management, and Treatment Recommendations

Reactions	Causative Agents	Treatment and Management
Cataracts	• Alkylating agents (busulfan) • Antiestrogens (tamoxifen) • Corticosteroids • Statins	Surgical removal of cataract
Dry eye	• Alpha-1 antagonists (alfuzosin, tamsulosin, terazosin) • Alpha-2 agonists (apraclonidine, brimonidine) • Anticholinergics (atropine, homatropine, hyoscine, ipratropium, tolterodine) • Anticonvulsants (valproic acid) • Antihistamines (cetirizine, chlorpheniramine, diphenhydramine, doxylamine) • Antimalarials (chloroquine, hydroxychloroquine) • Antineoplastics (busulfan, cyclophosphamide) • Antipsychotics (thioridazine) • Anxiolytics (lorazepam) • Beta-agonists (acebutolol) • Beta-blockers (atenolol, propranolol) • Benzalkonium chloride • Bisphosphonates • Cannabinoids (dronabinol) • Systemic decongestants (pseudoephedrine) • Diuretics (furosemide, indapamide, metolazone) • Oral contraceptives • Retinoids (isotretinoin) • Topical decongestants (naphazoline) • Tricyclic antidepressants (amitriptyline)	Nonpharmacologic therapy: ○ Warm compresses ○ Increase fluid intake ○ Use humidifier Increase tear volume: ○ Consider artificial tears or other topical lubricants ○ Punctal occlusion Decrease inflammation: ○ 0.05% cyclosporine ophthalmic drugs ○ LFA-1 antagonist ophthalmic drops ○ Short-term ophthalmic glucocorticoids Medication changes: ○ Discontinue medication ○ Use preservative-free ophthalmic drops

Floppy iris syndrome	- Alpha-1 antagonists
	- Benzodiazepines
	- Chlorpromazine
	- Donepezil
	- Duloxetine
	- Finasteride
	- Quetiapine
		- Preoperative screening for previous and/or current use of causative agents
		- Consider cataract surgery before initiation of alpha-1 antagonist therapy
		- Intracameral alpha-adrenergic agonists (epinephrine, phenylephrine)
		- Intraoperative devices:
		  ○ Iris retractors
		  ○ OVDs
		- Pupil expanders

Optic neuropathy	- Amiodarone - Ethambutol - Linezolid - PDE-5 inhibitors (avanafil, sildenafil, tadalafil, vardenafiil)	- Discontinuation of causative drug as medically appropriate - Regular ophthalmic examinations
Retinopathy	- Aminoquinolines (hydroxychloroquine, chloroquine) - Antiestrogens (tamoxifen) - Phenothiazines (chlorpromazine, thioridazine) - Retinoids (isotretinoin)	- Monitor via regular ophthalmic examinations, patient-reported signs and symptoms - Vision loss is irreversible

MANAGEMENT OF TOXICITY

⑥ Many cases of minor, drug-induced ophthalmic disorders resolve with dose reduction or discontinuation of the causative drug. At times, it is not possible to discontinue the offending drug, and supportive therapies may be necessary to manage symptoms until the primary agent is no longer needed. See Table e116-2 for a complete summary of common drug-induced ophthalmic disorders, causative agents, and recommendations on the appropriate management and/or treatment.

CONCLUSION

Drugs administered both systemically and/or topically have the potential to induce disorders of the eye. The severity may range from minor and temporary to severe and permanent. Clinicians must promptly examine any patient-reported side effects, establish causality with current medication therapy, discontinue medication as appropriate, and apply treatment as indicated to avoid damage to the eye.

ABBREVIATIONS

ADR	adverse drug reaction
DED	dry eye disease
DION	drug-induced optic neuropathy
IFIS	intraoperative floppy iris syndrome
LFA-1	lymphocyte function–associated antigen 1
OTC	over-the-counter
OVDs	ophthalmic viscosurgical devices
PDE-5	phosphodiesterase type-5
PDE-6	phosphodiesterase type-6

SELF-ASSESSMENT QUESTIONS

1. Drug reaction causality is best assessed using what approach?

A. Case reports

B. Naranjo scale

C. FDA bulletins

D. Prescription records

2. Which of the following drugs is most likely to cause floppy iris syndrome?

A. Metoprolol

B. Dexamethasone

C. Tamsulosin

D. Bevacizumab

3. Which structure of the eye contains photoreceptors that control color and night vision?

A. Retina

B. Cornea

C. Lens

D. Pupil

4. DED may occur with the use of which of the following medication classes?

A. Cholinergic agonists

B. ACE inhibitors

C. Bisphosphonates

D. Adrenergic agonists

5. Which of the following is most accurate regarding IFIS?

A. IFIS is more common in men than women.

B. Drug levels should be allowed to deplete prior to surgery to avoid IFIS.

C. Alpha-1 antagonists are the only class of medications associated with IFIS.

D. Postoperative screening should be done to assess risk for IFIS.

6. Which of the following is an acceptable treatment option for DED?

A. Topical decongestants

B. Intracameral epinephrine

C. Ophthalmic cyclosporine

D. Fluorescein drops

7. Patients suffering from DED may benefit from discontinuation of which medication from their regimen?

A. Dronabinol

B. Acetaminophen

C. Fluoxetine

D. Atorvastatin

8. Which of the following is the most appropriate strategy for prevention of drug-induced ophthalmic disorders?

A. Educate on signs and symptoms of ophthalmic side effects only if the patient asks.

B. Assess for risk factors after the patient has initiated therapy.

C. Avoid exceeding recommended daily or cumulative lifetime doses.

D. Encourage communication of only new prescription medications.

9. Which of the following is *not* an acceptable management strategy for DED?

A. Punctal occlusion

B. Dehumidifier use

C. Warm compress

D. Preservative-free ophthalmic products

10. Which best describes the mechanism of toxicity for ethambutol optic neuropathy?

A. Binds to melanin in retinal pigment epithelium

B. Competitively inhibits PDE-6 binding

C. Infiltrates vasculature creating deposit accumulation

D. Chelates copper required for mitochondria sufficiency

11. Which of the following is a risk factor for development of aminoquinoline retinopathy?

A. Family history

B. Normal body weight

C. Renal disease

D. Young age

12. What daily dose of hydroxychloroquine is associated with high risk of development of retinopathy?

A. 1 mg/kg/day

B. 3 mg/kg/day

C. 4 mg/kg/day

D. 6 mg/kg/day

13. Which of the following agents causes a posterior subscapular cataract?

A. Busulfan

B. Chlorpromazine

C. Linezolid

D. Chloroquine

14. Which medication toxicity presents as a bull's eye maculopathy?

A. Amiodarone

B. Thioridazine

C. Tamoxifen

D. Hydroxychloroquine

15. Which of the following classes does *not* cause retinopathy?

A. Phenothiazines

B. Anti-estrogenic agents

C. Retinoids

D. Beta-adrenergic antagonists

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Naranjo is the most appropriate source to establish causality between an adverse event and medication therapy.

2. **C.** Tamsulosin is an alpha-adrenergic antagonist. This class of medications is known to cause floppy iris syndrome. See section "Drug-Induced Ophthalmic Reactions" for more information.

3. **A.** Retina contains photoreceptors responsible for vision detail, color vision, and night vision.

4. **C.** Bisphosphonates are known to cause dry eye. Cholinergic agonists and adrenergic agonists increase tear production and are not associated with DED. DED is not a known adverse effect of ACE inhibitors.

5. **A.** IFIS is more common in men than women, likely due to greater use of alpha-1 antagonists. B, C, and D are not correct. IFIS development is observed in patients who have not received an alpha-1 antagonist for quite some time. Allowing depletion of alpha-1 antagonist levels will not provide decreased risk of developing IFIS. Other medication classes besides alpha-1 antagonists have been associated with the development of IFIS. Preoperative screening should be done to assess risk for IFIS.

6. **C.** Ophthalmic cyclosporine is an acceptable option to treat inflammation associated with dry eye. Topical decongestants will exacerbate DED. Intracameral epinephrine is indicated for IFIS and not DED. Fluorescein drops are not appropriate for the management of DED and are best suited for eye examination.

7. **A.** Dronabinol is a cannabinoid associated with DED.

8. **C.** Avoid exceeding recommended daily or cumulative lifetime doses, especially if specific dose thresholds have been implicated in increasing the risk of ophthalmic disorder. Risk factors should be assessed prior to initiating therapy. Education on signs and symptoms should always be done, not only upon request of the patient. Patients should report any new prescription, herbal, and OTC medications that may increase the risk of ophthalmic disorder.

9. **B.** Dehumidifiers decrease the amount of moisture in the air, which may exacerbate dry eye.

10. **D.** Ethambutol chelates copper required for mitochondrial sufficiency.

11. **C.** Renal disease is a known risk factor for development of aminoquinolines retinopathy.

12. **D.** Hydroxychloroquine doses greater than 5 mg/kg/day is associated with a high risk for development of retinopathy.

13. **A.** Busulfan has the potential to cause a posterior subscapular cataract. Chlorpromazine may induce a central anterior cataract, while linezolid and chloroquine are not known to induce cataracts.

14. **D.** A bull's eye maculopathy indicates hydroxychloroquine as the causative agent.

15. **D.** Beta-adrenergic antagonists are not known to cause retinopathy. Phenothiazines, antiestrogen agents, and retinoids do have the potential to induce retinopathy.

Chapter e125: Drug-Induced Hematologic Disorders

Elisa M. Greene; Tracy M. Hagemann

KEY CONCEPTS

KEY CONCEPTS

① The most common drug-induced hematologic disorders are aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.

② Drug-induced hematologic disorders are rare adverse drug reactions (ADRs) associated with drug therapy.

③ The incidence of rare ADRs is usually established by postmarketing surveillance and reporting.

④ Rechallenging a patient with an agent suspected of inducing a blood disorder is not generally recommended.

⑤ Drug-induced hematologic disorders can occur by two mechanisms: direct drug or metabolite toxicity or an immune reaction.

⑥ The primary treatment of drug-induced hematologic disorders is the removal of the drug in question and symptomatic support of the patient.

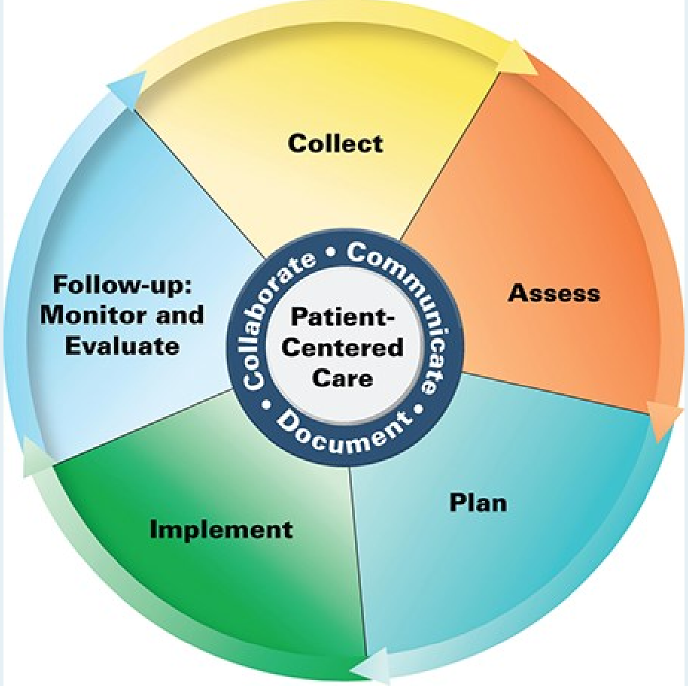
BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “Part 1: Anemia: Pathophysiology and Diagnostic Approach” (https://accessmedicine.mhmedical.com/MultimediaPlayer.aspx?MultimediaID=16442308) in AccessMedicine by Scott Stern, MD. This can be found by clicking on Multimedia, Lectures, Diagnostic Reasoning, then Part 1: Anemia (https://accessmedicine.mhmedical.com/MultimediaPlayer.aspx?MultimediaID=16442308). This 21-minute video provides an overview of the foundational knowledge of anemia, the approach to evaluate a patient with anemia, common causes of anemias, and differential diagnosis for different types of anemias. This video increases student understanding regarding the COLLECT and ASSESS steps in the patient care process.

PATIENT CARE PROCESS

Patient Care Process for Drug-Induced Hematologic Disorders



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Medication history
- ADR probability scale data
- Laboratory data (eg, CBC, antibody tests)
- Medication history (eg, has the patient taken heparin? What is the timing?)

Assess

- Determine probable cause and severity of illness based on information above (eg, how likely is heparin-induced thrombocytopenia based on the Naranjo Algorithm? Have bleeding or thrombotic complications arisen?)

Plan[*]

- Determine alternate and additional therapy if indicated (eg, which alternative anticoagulant should be chosen? Is there a preference for IV, SQ, or PO therapy? Is there a contraindication to argatroban? If severe bleeding is present, should corticosteroids, IVIG, or blood transfusions be considered?)

Implement

- Remove suspected causative agent and replace as needed (eg, stop heparin, start argatroban)

Follow-up: Monitor and Evaluate

- Reassess clinical and laboratory data (eg, CBC to ensure that platelet counts recover appropriately)
- Consider appropriateness of transition to SQ or PO anticoagulation
- Continue to follow pertinent parameters to ensure resolution (eg, daily CBCs while patient is hospitalized with goal of platelet recovery within 1 week)

- Continue anticoagulation at least 2 to 3 weeks to minimize ongoing risk of thrombosis
- Evaluate over time (eg, has the situation been resolved satisfactorily? Is additional therapy or action needed? In the future, what could be changed to provide better care in similar situations?)

See Introduction and Drug-Induced Thrombocytopenia (Clinical Presentation and Management of Toxicity) sections for more information related to the patient care process.

INTRODUCTION

① Hematologic disorders have long been a potential risk of modern pharmacotherapy. Granulocytopenia (agranulocytosis) was reported in association with one of medicine's early therapeutic agents, sulfanilamide, in 1938.[1] Some agents cause predictable hematologic disease (eg, antineoplastics), but others induce idiosyncratic reactions not directly related to the drugs' pharmacology. The most common drug-induced hematologic disorders are aplastic anemia, agranulocytosis, megaloblastic anemia, hemolytic anemia, and thrombocytopenia.

② The incidence of idiosyncratic drug-induced hematologic disorders varies depending on the condition and the associated drug. Few epidemiologic studies have evaluated the actual incidence of these adverse reactions, but these reactions are rare. Women are generally more susceptible than men to the hematologic effects of drugs. The incidence varies based on geography, which suggests that genetic differences may be important determinants of susceptibility. Drug-induced thrombocytopenia is the most common drug-induced hematologic disorder, with reports suggesting that between 0.1% and 5% of patients who receive heparin develop heparin-induced thrombocytopenia (HIT).[2,3] The Berlin Case-Control Surveillance Study was conducted from 2000 to 2009 to assess the incidence and risks of drug-induced hematologic disorders and found that almost 30% of all cases of blood dyscrasias were "possibly" attributable to drug therapy.[4]

Although drug-induced hematologic disorders are less common than other types of adverse reactions, they are associated with significant morbidity and mortality. Aplastic anemia is the leading cause of death followed by thrombocytopenia, agranulocytosis, and hemolytic anemia.[5] Similar to most other adverse drug reactions (ADRs), drug-induced hematologic disorders are more common in older individuals than in the young; the risk of death is also greater with increasing age.

③ The MedWatch program supported by the Food and Drug Administration (FDA)[6] is the most common avenue for postmarketing surveillance to establish the incidence of ADRs. The FDA's Adverse Event Reporting System (FAERS) is the database that contains the reports submitted to the FDA and supports the post-marketing safety and surveillance program for both drug and therapeutic biologic products. It has a dashboard that allows the public to search for human adverse events that have been reported by the pharmaceutical industry, healthcare providers, and consumers. Many facilities have similar drug-reporting programs to follow ADR trends and to determine whether an association between a drug and an ADR is causal or coincidental. These programs enable practitioners to confirm that an adverse event is the result of drug therapy rather than one of many other potential causes; general guidelines are readily available.[7,8]

④ Because drug-induced blood disorders are potentially dangerous, rechallenging a patient with a suspected agent in an attempt to confirm a diagnosis is not recommended. In vitro studies with the offending agent and cells or plasma from the patient's blood can be performed to determine causality.[9] These methods are often expensive, however, and require facilities and expertise that are not generally available. Although the diagnosis of HIT requires laboratory testing,[10] laboratory confirmation of drug causation is not always necessary to warrant interruption or discontinuation of therapy. Therefore, it is extremely important that clinicians be able to clinically evaluate suspect drugs quickly and to interrupt therapy when necessary.

Through the use of surveillance programs, lists of drugs that may be associated with adverse events have been published. These lists include a large number of commonly used drugs. Although these lists may help clinicians identify specific drug causes of adverse events, the large number of agents implicated may make this a difficult process. The absence of a drug from such a list should not discourage the investigation and reporting of a suspected agent associated with an adverse event. It is imperative that clinicians use a rational approach to determine causality and identify the agents associated with a reaction. The clinician should focus on the issue, perform a rigorous investigation, develop appropriate criteria, use objective criteria to grade the response, and complete a quantitative summary. A complete, thorough, and detailed drug and exposure history must be obtained from the patient in order to best determine any potential for drug causation.

A common tool used to rate the likelihood of causality in ADR investigations is the ADR probability scale (algorithm). One such scale was developed and tested by Naranjo et al.[11] This tool provides a series of scored questions that lead an investigator to the likelihood that an ADR was caused by the suspected medication. Depending on the aggregate score, the causality is rated as *doubtful, possible, probable,* or *definite*. The scale gives the most weight to the temporal relationship of the reaction with relation to administration of the drug, observations after a rechallenge of the suspected medication, and alternate explanations for the ADR. As mentioned earlier, it is often unethical to rechallenge patients who experience severe hematologic toxicities. Thus, without a rechallenge, it is difficult to achieve a causality rating of *definite* with such an algorithm.

In determining the likelihood that an observed reaction is caused by a particular medication, clinicians should review the medical literature for past reports supporting the observation. Greater weight should be assigned to prospective study designs such as clinical trials or cohort studies than to case reports or expert opinion.

Evaluating drug-induced hematologic disorders requires a basic understanding of hematopoiesis (see Chapter e106, "Function and Evaluation of the Immune System"). The pluripotent hematopoietic stem cells in the bone marrow self-reproduce in order to maintain the blood. These cells further differentiate into intermediate precursor cells, which are also called progenitor cells or colony-forming cells. Committed to a particular cell line, these intermediate stem cells differentiate into colonies of each type of blood cell in response to specific colony-stimulating factors. Drug-induced hematologic disorders can affect any cell line, including white blood cells (WBCs), red blood cells (RBCs), and platelets. When a drug causes decreases in all three cell lines accompanied by a hypoplastic bone marrow, the result is drug-induced aplastic anemia. The decrease in WBC count alone by a medication is drug-induced agranulocytosis. Drugs can affect RBCs by causing a number of different drug-induced anemias, including immune hemolytic anemia, oxidative hemolytic anemia, or megaloblastic anemia (see Chapter 122, "Anemias"). A drug-induced decrease in platelet count is drug-induced thrombocytopenia.

DRUG-INDUCED APLASTIC ANEMIA

Aplastic anemia is a rare, serious disease of unclear etiology characterized by pancytopenia (anemia, neutropenia, and thrombocytopenia),[12] hypocellular bone marrow and no gross evidence of increased peripheral blood cell destruction.[13] Bone marrow examination shows an absence or marked reduction of hematopoietic stem cells and an increase in fat cells.

The incidence is estimated to be about two per million per year in Europe and North America, and four to six per million per year in Asia, which suggests a relationship between the environment and risk.[14] Fifty percent of aplastic anemia cases are acquired in nature, but a definitive causative agent cannot be identified in most cases.[15,16] Men and women are affected equally, but there is a bimodal risk distribution when it comes to age, with peak incidences in those aged 10 to 25 years and again in those older than 60 years.[16]

Diagnosis and Classification

The diagnosis of aplastic anemia requires the presence of two of the following criteria: a WBC count of 3,500 cells/mm^3 (3.5 × 10^9/L) or less, a platelet count of 55,000 cells/mm^3 (55 × 10^9/L) or less, or a hemoglobin value of 10 g/dL (100 g/L; 6.21 mmol/L) or less with a reticulocyte count of 30,000 cells/mm^3 (30 × 10^9/L) or less.[17] Depending on the blood counts, aplastic anemia can be categorized as moderate, severe, and very severe aplastic anemia.[17,18]

- Moderate aplastic anemia (MAA): Two of the following three criteria—neutrophils less than 1,500 cells/mm^3 (1.5 × 10^9/L), platelets less than 50,000 cells/mm^3 (50 × 10^9/L), and hemoglobin less than 10 g/dL (100 g/L; 6.21 mmol/L).
- Severe aplastic anemia (SAA): Two of the following three criteria—neutrophils less than 500 cells/mm^3 (0.5 × 10^9/L), platelets less than 20,000 cells/mm^3 (20 × 10^9/L), and reticulocytes less than 1%.

- Very severe aplastic anemia (VSAA): SAA with a neutrophil count less than 200 cells/mm^3 (0.2 × 10^9/L).

The diagnosis of aplastic anemia requires a bone marrow aspirate and biopsy to exclude other causes of pancytopenia.[17] The patient must not have had previous exposure to cytotoxic chemotherapy or intensive radiation.

Mechanism

Aplastic anemia can be divided into two broad categories, inherited and acquired. Inherited aplastic anemias, such as Fanconi's and Blackfan Diamond, result in bone marrow failure, fatty infiltration of the marrow, and loss of circulating blood cells. Acquired aplastic anemia is the focus of this section because it is the type of aplastic anemia that results from drugs, radiation, viruses, or chemical exposure, and it accounts for most cases of aplastic anemia. Acquired, drug-induced aplastic anemia is an idiosyncratic reaction, with unpredictable severity and time to recovery.

⑤ Three major mechanisms of acquired aplastic anemia have been identified: direct toxicity, metabolite-driven toxicity, and immune-mediated mechanisms.[18] Idiosyncratic drug-induced aplastic anemia secondary to direct toxicity can be characterized by dose independence, a latent period before the onset of anemia, and continued marrow injury after drug discontinuation.[19] When intermediate metabolites of drugs bind to proteins and DNA on hematopoietic cells, bone marrow failure can occur. Genetic variation leads to variability in the presence of these reactive metabolites and explains the idiosyncratic nature of these drug reactions. The most common cause of drug-induced aplastic anemia is the development of an immune reaction. The exposure to an inciting antigen (ie, drug) activates the immune system, leading to the death of stem cells.[18] The immune mechanism of aplastic anemia explains the responsiveness of the disease to immunosuppressive therapy.[18]

Genetic predisposition can also influence the development of drug-induced aplastic anemia.[20] Pharmacogenetic research to identify patients who are abnormal metabolizers of drugs can increase the clinician's ability to predict the development of aplastic anemia. Observational studies have not demonstrated a significant difference between control participants and cases, but continued research may establish the role of altered metabolism in patients with aplastic anemia.[20]

Causative Agents

Table e125-1 shows a list of medications that have been associated with drug-induced aplastic anemia. Cytotoxic chemotherapy and radiation therapy can induce varying degrees of bone marrow suppression or failure. The antineoplastic agents exemplify the dose-dependent mechanism for the development of aplastic anemia. Many of these agents suppress one or more cell lines in a reversible manner. The degree of suppression and the cell line involved depend on the nature of the particular drug and its potential for inhibiting marrow proliferation. Certain chemicals or agents may also induce direct injury to hematopoietic cells.

TABLE e125-1

Drugs Associated with Aplastic Anemia

Observational study evidence
Carbamazepine
Furosemide
Gold salts
Mebendazole
Methimazole
NSAIDs
Oxyphenbutazone
Penicillamine
Phenobarbital
Phenothiazines
Phenytoin
Propylthiouracil

Sulfonamides
Thiazides
Tocainide
Case report evidence (*probable* or *definite* causality rating)
Acetazolamide
Aspirin
Captopril
Chloramphenicol
Chloroquine
Chlorothiazide
Chlorpromazine
Dapsone
Felbamate
Interferon alfa
Lisinopril
Lithium
Nizatidine
Pentoxifylline
Quinidine
Sulindac
Temozolomide
Ticlopidine
MedWatch postmarketing reports 2009-2020
Adalimumab
Aliskirin
Amlodipine
Carvedilol
Dantrolene
Etanercept
Infliximab
Oxcarbazepine
Pembrolizumab
Posaconazole
Valsartan

NSAIDs, nonsteroidal anti-inflammatory drugs.

Chloramphenicol, already known to cause a dose-dependent reaction, is the prototype drug for the idiosyncratic mechanism. The estimated incidence of chloramphenicol-induced aplastic anemia is one case per 20,000 patients treated, but the overall prevalence has declined with decreased use of this agent.[19] The dose-dependent and idiosyncratic reactions seen with chloramphenicol are not related. Other drugs thought to induce aplastic anemia through toxic metabolites include phenytoin and carbamazepine. The metabolites of these medications bind covalently to macromolecules in the cell and then cause cell death either by exerting a direct toxic effect on the stem cell or by causing the death of lymphocytes involved in regulating hematopoiesis.[21]

Management of Toxicity

Rapid diagnosis and immediate therapy initiation are important because of the high mortality rate associated with SAA and VSAA. Treatment should be based on the severity of disease, with the goal of therapy being to improve peripheral blood counts, limit the requirement for transfusions, and minimize the risk for infections.

6 As with all cases of drug-induced hematologic disorders, the first step is to remove the suspected offending agent. Early withdrawal of the drug can allow for reversal of the aplastic anemia. Appropriate supportive care is also essential because the major causes of mortality in patients with aplastic anemia are infections (bacterial and fungal) and bleeding. Patients must receive transfusion support with erythrocytes and platelets, as well as appropriate antimicrobial prophylaxis or treatment during neutropenic periods. Routine use of growth factors such as recombinant human erythropoietin and granulocyte colony-stimulating factor (G-CSF) does not improve outcomes and is not recommended for the management of aplastic anemia except when life-threatening infections are present.[12] Current treatment guidelines for aplastic anemia recommend the use of prophylactic antibiotics and antifungal agents when neutrophil counts are below 500 cells/mm^3 (0.5 × 10^9/L). If patients experience febrile neutropenia, broad-spectrum intravenous antibiotics should be started immediately. Current guidelines do not recommend the use of prophylaxis for viruses or *Pneumocystis jiroveci*. For patients who have been heavily transfused, iron chelation therapy with agents such as deferoxamine or deferasirox may be necessary to avoid the serious consequences of iron overload.

The major treatment options for patients with drug-induced aplastic anemia are allogeneic hematopoietic stem cell transplantation (HSCT) and immunosuppressive therapy. Factors that determine which therapy would be preferred include age, disease severity, and availability of a human leukocyte antigen (HLA)–matched donor. For healthy patients younger than 50 years, the treatment of choice is allogeneic HSCT from an HLA-matched sibling donor. This is associated with potential cure and results in a 5-year survival rate of 77% in adults and up to 90% in children.[12,22,23] Unfortunately, most patients do not have a matched sibling donor and so allogeneic HSCT from an HLA-matched unrelated donor may be considered, but it is usually reserved for those who fail prior immunosuppressive therapy. When used in this setting, the 5-year overall survival rate in these patients has improved to over 50%, primarily because of improvements in HLA typing and unrelated donor selection.[24,25] For patients older than 50 years and for those who are not candidates for transplant due to comorbidities or no available match, the preferred first-line therapy is immunosuppressive therapy.[12] Complications of allogeneic HSCT, such as graft-versus-host disease and graft rejection, require all patients to be closely monitored for an extended period of time.

The standard immunosuppressive regimen for the treatment of MAA that does not respond to supportive care is combination therapy with antithymocyte globulin (often referred to as ATG) and cyclosporine. This combination has been reported to achieve 5-year survival rates between 75% and 85%, but the response rate in older individuals is lower.[26] Although cyclosporine monotherapy has been used to treat MAA, the combination of these agents increase response rate, improve failure-free survival, and reduce the number of immunosuppressive courses needed.[27,28] Cyclosporine inhibits interleukin-2 production and release and subsequent activation of resting T cells. Cyclosporine dosing has varied from 4 to 6 mg/kg/day to 10 to 12 mg/kg/day, with the most frequently reported initial dose of 5 mg/kg/day in two divided doses. Cyclosporine doses are titrated to a target blood concentration that can be patient- and institution-specific but is usually in the range of 150 to 250 μg/L (125-208 nmol/L) for adult patients. Cyclosporine should be continued for at least 12 months after response and then tapered slowly, as increased relapse rates have been observed when tapering rapidly.[26] Antithymocyte globulin is composed of polyclonal immunoglobulin G (IgG) against human T lymphocytes derived from either horses or rabbits and has been a standard component of immunosuppressive therapy for aplastic anemia for many years. In one study comparing the horse versus rabbit product, both given in combination with cyclosporine, treatment with the horse-derived antithymocyte globulin product resulted in significantly higher response rates (68% vs 37%) and 3-year overall survival rates (96% vs 76%). Although the mechanism for this difference is not completely understood, the greater depletion of CD4$^+$ cells associated with the rabbit antithymocyte globulin as compared with horse antithymocyte globulin may be associated with adverse outcomes. However, other studies found no difference between formulations.[12,29] Based on these results, treatment with the horse-derived antithymocyte globulin product may be preferred for treatment when available. Because response to immunosuppressive therapy is often delayed (3-4 months), patients require continued supportive care until recovery. Patients should be monitored for ADRs, including serum sickness, which can occur about 1 week after antithymocyte globulin begins.[26]

Corticosteroids are added to antithymocyte globulin-based immunosuppression because of their ability to reduce adverse reactions associated with antithymocyte globulin administration. In an effort to improve outcomes, several other agents have also been investigated in the treatment of aplastic anemia. The additive benefits of other immunosuppressive agents such as mycophenolate, cyclophosphamide, and sirolimus have been evaluated.[22] However, they have not been shown to be superior to the combination of antithymocyte globulin and cyclosporine, and their place in therapy is not clearly defined. In the case of refractory or relapsed disease, a second cycle or an alternative agent, such as alemtuzumab or high-dose cyclophosphamide, may be able to achieve a remission rate of 50%.[12]

The addition of G-CSF to the combination of antithymocyte globulin and cyclosporine results in high response rates but does not prolong survival as compared with antithymocyte globulin and cyclosporine.[28,30-32] However, one study indicated that in patients receiving this combination, the neutrophil count on day +30 predicted response and survival.[32] This may allow for early recognition of those patients who are not likely to respond to therapy and lead to earlier transplants in those affected.[33] Eltrombopag, a thrombopoietin nonpeptide agonist, is used as first-line therapy in the treatment of SAA in combination with antithymocyte globulin and cyclosporine. In one study in 88 patients, the response rate at 6 months was 85% and survival approached 90%.[34] Another trial showed similar response rates at 6 months, and at a median follow-up of 2 years, had a survival rate of 97%.[35] Initial dose is 50 mg orally once daily and is titrated based on platelet response. Initially, the dose is 150 mg orally once daily and is titrated based on platelet response; however, patients of Asian ethnicity should be initiated at a dose of 75 mg once daily. This is due to an increased plasma exposure seen in trials. A review of use in 22 Japanese patients with AA refractory to immunosuppressive therapy found a significant improvement in 47.6% of patients at 6 months. Patients were initiated on a dose of 25 mg once daily, then titrated every 2 weeks to a maximum of 100 mg daily.[36]

DRUG-INDUCED AGRANULOCYTOSIS

Agranulocytosis is defined as a reduction in the number of mature myeloid cells in the blood (granulocytes and immature granulocytes [bands]) to a total count of 500 cells/mm^3 (0.5 × 10^9/L) or less. The incidence ranges from 1.6 to 9.2 cases per million in Europe and 2.4 to 15.4 cases per million in the United States.[37,38] Older patients are thought to be at greater risk for drug-induced agranulocytosis, most likely due to increased medication use.[38,39] Drug-induced agranulocytosis also occurs more frequently in women than in men.

Clinical Presentation

Agranulocytosis is a rare reaction that typically presents with fever. Symptoms arise from the increased infection risk associated with the lack of WBCs and include sore throat, fever, malaise, weakness, and chills. Agranulocytosis may develop 19 to 60 days after exposure of the offending drugs but typical time of onset is at least 1 month after drug initiation. Symptoms may appear either immediately or insidiously, depending on the time course of neutropenia development.[40]

Mechanism

⑤ The cause of drug-induced agranulocytosis is not fully understood, but two mechanisms—direct toxicity and immune-mediated toxicity—have been proposed. Direct toxicity may be due to either the parent drug or a toxic metabolite or byproduct. Agranulocytosis associated with direct toxicity is usually associated with a slower decline in neutrophils, with a more insidious presentation of symptoms.[41,42] With immune-mediated mechanisms, agranulocytosis occurs within days to a few weeks after drug exposure, with rapid appearance of symptoms.[42] Within the immune-mediated subset of agranulocytosis, three mechanisms of toxicity have been proposed. The *hapten mechanism* involves the drug or its metabolite binding to the membrane of neutrophils or myeloid precursors. After binding, antibodies are induced that destroy the cell.

In the *immune-complex mechanism*, antibodies form complexes with the causative drug, and the immune complex adheres to the target cell, leading to cell destruction. Finally, in the *autoimmune mechanism*, the drug triggers the production of autoantibodies that react with neutrophils. In this reaction, the causative drug is not directly involved with the serologic reaction. In all mechanisms, cell destruction occurs via antibody-mediated cell toxicity, complement activation, and phagocytic elimination through the mononuclear phagocytic system.

Causative Agents

A list of medications that have been associated with drug-induced agranulocytosis can be seen in Table e125-2. Antipsychotics, antibiotics, and antithyroid medications are commonly implicated.[43] Nearly all classes of drugs have been associated with some incidence of acute neutropenia or agranulocytosis, but the risk is exceedingly small. The risk may be higher for some drugs, such as antithyroid medications (propylthiouracil and methimazole), ticlopidine, clozapine, sulfasalazine, trimethoprim–sulfamethoxazole, deferapirone, and β-lactam antibiotics. Mechanisms associated with selected agents can be seen in Table e125-3.

TABLE e125-2

Drugs Associated with Agranulocytosis

Observational Study Evidence	Case Report Evidence (*Probable* or *Definite* Causality Rating)		MedWatch Postmarketing Reports 2009-2020
β-Lactam antibiotics	Acetaminophen	Levodopa	Amlodipine
Carbamazepine	Acetazolamide	Meprobamate	Bocepravir
Carbimazole	Ampicillin	Methazolamide	Clozapine
Clomipramine	Aripiprazole	Methyldopa	Defarasirox
Digoxin	Captopril	Metronidazole	Fluoxetine
Dipyridamole	Carbenicillin	Nafcillin	Haloperidol
Ganciclovir	Cefepime	NSAIDs	Hydrochlorothiazide
Glyburide	Cefotaxime	Octreotide	Iacosamide
Gold salts	Ceftriaxone	Olanzapine	Ibrutinib
Imipenem–cilastatin	Cefuroxime	Oxacillin	Leflunomide
Indomethacin	Chloramphenicol	Penicillamine	Levitiracetam
Macrolide antibiotics	Chlorpromazine	Penicillin G	Linezolid
Methimazole	Chlorpropamide	Pentazocine	Memantine
Mirtazapine	Chlorpheniramine	Phenytoin	Metformin
Phenobarbital	Clindamycin	Primidone	Molindone
Phenothiazines	Clozapine	Procainamide	Olanzapine
Prednisone	Colchicine	Propylthiouracil	Oseltamivir
Propranolol	Doxepin	Pyrimethamine	Oxcarbazepine
Spironolactone	Dapsone	Quinidine	Paliperidone
Sulfonamides	Desipramine	Quinine	Pantoprazole
Sulfonylureas	Ethacrynic acid	Rifampin	Pimozide
Ticlopidine	Ethosuximide	Streptomycin	Propafenone
Valproic acid	Flucytosine	Terbinafine	Quetiapine

Zidovudine	Gentamicin	Ticarcillin	Rifabutin
	Griseofulvin	Tocainide	Risperidone
	Hydralazine	Tolbutamide	Rituximab
	Hydroxychloroquine	Valganciclovir	Sulfasalazide
	Imipenem–cilastatin	Vancomycin	Thiothixene
	Imipramine		Tocilizumab
	Lamotrigine		Trandolapril
			Ustekinumab
			Ziprasidone

NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE e125-3

Mechanisms of Drug-Induced Agranulocytosis

Direct Toxicity to Myeloid Cells	Hapten Mechanism	Immune Complex Mechanism	Autoimmune Mechanism
Chlorpromazine	Aminopyrine	Quinine	Levisamole
Procainamide	Penicillin	Quinidine	
Clozapine	Gold compounds		
Dapsone			
Sulfonamides			
Carbamazepine			
Phenytoin			
Indomethacin			
Diclofenac			

The mechanism by which antithyroid agents cause agranulocytosis is unknown, but antineutrophil cytoplasmic antibodies have been identified.[44] Agranulocytosis occurs more frequently in patients older than 40 years and within 2 months after the initiation of therapy. Although a possible dose-response relationship has been reported,[45] agranulocytosis has been associated with long-term low doses of propylthiouracil and methimazole treatment.[46] Recent studies have identified genetic variants associated with the development of antithyroid drug-induced agranulocytosis in several different ethnic groups.[47] Genome-wide association studies have shown an association between agranulocytosis induced by antithyroid drugs and the HLA alleles *HLA-B*38:02* and *HLA-DRB1*08:03* in ethnic Chinese.[48] In a study in white European adults, agranulocytosis associated with antithyroid drug use was associated with *HLA-B*27:05*.[49] Additional investigations have associated agranulocytosis with these drugs in Taiwanese (*HLA-B*38:02* and *HLA-DRBI*0803*) and Vietnamese (*HLA-B*38:02*) populations.[50,51] These findings may help clinicians in the future to better monitor and manage therapy in those requiring antithyroid medications.

Ticlopidine produces neutropenia in about 2.4% and agranulocytosis in 0.8% of patients, possibly by inhibiting hematopoietic progenitor stem cells.[52] Agranulocytosis associated with ticlopidine most commonly occurs within 1 to 3 months from the initiation of the drug.

Clozapine is associated with a significantly higher risk of agranulocytosis compared with other antipsychotic medications.[53] Because of the frequency and seriousness of this effect and its reversible nature if detected early, clozapine is only available through a limited distribution program that requires strict monitoring of WBC count.[54]

The phenothiazine class of drugs is known to cause drug-induced agranulocytosis by the immune-complex mechanism. When the bone marrow from a patient with phenothiazine-induced agranulocytosis is examined, it initially has no cellularity (aplastic), but it eventually becomes hyperplastic. It is believed that the toxic effects of the phenothiazines are not seen in all patients taking the medications because most patients have enough bone marrow reserve to overcome the toxic effects.[55] The onset of phenothiazine-induced agranulocytosis is about 2 to 15 weeks after the initiation of therapy, with a peak onset between 3 and 4 weeks.[56]

Penicillin derivatives may suppress WBCs by several mechanisms. Although the hapten mechanism is suspected to be the cause of penicillin-induced agranulocytosis because of the rapid onset of symptoms and the dose-related phenomenon, a second mechanism could possibly be involved. That mechanism involves an accumulation of drug to toxic concentrations in hypersensitive individuals. Researchers have shown with in vitro cell cultures that penicillin derivatives in high concentrations inhibit the growth of myeloid colony-forming units (CFUs) in patients recovering from drug-induced agranulocytosis.[57]

Management of Toxicity

6 Removal of the drug is the best treatment option, with blood cell counts usually returning to normal within 2 to 4 weeks. Sargramostim (granulocyte-macrophage colony-stimulating factor, or GM-CSF) and filgrastim (G-CSF) shorten the duration of neutropenia, length of antibiotic therapy, and hospital length of stay.[58] Although the use of both agents has been reported in the literature, a commonly used regimen is G-CSF 300 μg/day via subcutaneous injection. Most clinicians recommend the use of growth factors in patients with a neutrophil nadir less than 100 cells/mm^3 (0.1×10^9/L), regardless of the presence of infection.

The overall mortality rate of agranulocytosis has fallen dramatically over the past 20 years largely because of improvements in infection prophylaxis and supportive care.[37,40] The mortality rate is highest among older individuals and patients with renal failure, bacteremia, or shock at the time of diagnosis.[37,39-41] Drug-induced agranulocytosis usually resolves over time with supportive care and management of infection. The time to neutrophil recovery has typically been reported to range from 4 to 24 days.[40] Restarting the drug is not usually recommended. In the case of penicillin-induced agranulocytosis, the patient can often begin taking penicillin again, at a lower dosage, after the neutropenia has resolved without any recurrence of drug-induced agranulocytosis.[59]

DRUG-INDUCED HEMOLYTIC ANEMIA

After their release from the bone marrow, normal RBCs survive for about 120 days before they are removed by phagocytic cells in the spleen and liver. The process of premature red blood cell (RBC) destruction is referred to as hemolysis, which can occur because of either defective RBCs or abnormal changes in the intravascular environment. Drugs can promote hemolysis by both processes.

The incidence of drug-induced hemolytic anemia is estimated to be about one in 1 to 2 million individuals, although the exact incidence has been difficult to ascertain because of difficulty in establishing a clear diagnosis and relationship to a specific agent.[60]

Clinical Presentation

The onset of drug-induced hemolytic anemia is variable and depends on the drug and mechanism of the hemolysis. Symptoms of hemolytic anemia can include fatigue, malaise, pallor, and shortness of breath. Patients may present with abdominal pain, lumbar pain, or red urine as a result of hemolysis.[61]

Diagnosis

The best means to diagnose drug-induced immune hemolytic anemia is with the direct Coombs test (or direct antiglobulin test [DAT]), which identifies foreign immunoglobulins either in the patient's serum or on the RBCs themselves. The direct Coombs test involves combining the patient's RBCs with antiglobulin serum. This serum is created by injecting rabbits with preparations of human complement, crystallizable fragment (of immunoglobulin [Fc]), or immunoglobulins. The rabbits then produce antibodies against human immunoglobulins and complement, which becomes the antiglobulin serum. In a drug-induced process, the patient's RBCs are coated with antibody or complement and the antibodies in the antiglobulin serum attach to the separate RBCs, creating a lattice formation called agglutination.[62] This agglutination is considered positive for the presence of IgG or complement on the cell surfaces.

An indirect Coombs test can identify the presence of antibodies in a patient's serum. This test is performed by combining the patient's serum with normal RBCs and then subjecting them to the direct Coombs test. This process is important in blood bank procedures.

Mechanism

⑤ The mechanism of drug-induced hemolytic anemia can be divided into two categories, immune or metabolic (ie, oxidative).

Immune

In immune hemolytic anemia, IgG, immunoglobulin M (IgM), or both bind to antigens on the surface of RBCs and initiate their destruction through the complement and mononuclear phagocytic systems.[63] Immunologic mechanisms can be either drug dependent or independent.[64]

Drug Dependent

The drug-dependent mechanism is most common and involves the formation of antibodies directed against RBCs. In this scenario, antibodies are only present when the drug itself is present.[64]

Four mechanisms have been proposed to explain how drugs can induce immune hemolytic anemia; these are similar to those proposed for drug-induced agranulocytosis.[65]

The first mechanism is the "hapten mechanism" or "drug adsorption" mechanism. Haptens are drugs or molecules that cause an immune response when they bind to a protein in the body. In this mechanism, patients make an antibody against a stable complex of the drug with some soluble noncellular molecule or protein. When the drug is administered again, an immune complex of drug–antidrug forms and attaches nonspecifically to RBCs, activating complement and leading to cell destruction.[65] The anemia usually develops gradually over 7 to 10 days and reverses over a couple of weeks after the offending drug is discontinued. The direct Coombs test result may remain positive for several weeks.

The second mechanism is the immune complex or "innocent bystander" mechanism. In this mechanism, drugs bind to an antibody, usually IgM, to form an immune complex. This immune complex then attaches to the RBC membrane, activating complement and leading to intravascular hemolysis.[65] As soon as complement is activated, the complex can detach and move on to other RBCs. Because of this low affinity, only a small amount of drug is needed to cause the reaction, and the direct Coombs test result is positive for complement only. RBCs are essentially victims, or "innocent bystanders," of the immunologic reaction. This mechanism is associated with acute intravascular hemolysis that can be severe, sometimes leading to hemoglobinuria and renal failure. After clearance of the drug from the circulation, the direct Coombs test result will become negative.

The third mechanism involves the production of true RBC autoantibodies. The mechanism for autoantibody production is poorly understood, although two hypotheses have been proposed.[66] The first suggests that the medication or its metabolites act on the immune system and impair immune tolerance. An alternative hypothesis is that the offending drug may bind to immature RBCs, altering the membrane antigens and inducing autoantibodies. Methyldopa is the prototype drug for this mechanism. About 10% to 20% of patients receiving methyldopa will develop a positive

Coombs test, usually within 6 to 12 months of initiating therapy.[67] However, less than 1% of these patients experience hemolysis, and hemolysis can develop from 4 to 6 months to more than 2 years after the start of therapy. After the withdrawal of the drug, results of the Coombs test can remain positive for many months.[67] Because of the autoantibodies produced, methyldopa is often considered to cause autoimmune hemolytic anemia.[68] It is not known why only some patients develop autoantibodies and why only some of the patients who have autoantibodies develop hemolytic disease.

The fourth mechanism of drug-induced immune hemolytic anemia is through nonimmunologic protein adsorption to RBC membranes.[65] In this “membrane modification mechanism,” drugs can change the RBC membrane so that proteins attach to the cell, leading to a positive antiglobulin test result. This phenomenon was originally thought to be important only because of laboratory test interference.

Drug Independent

Drug-independent mechanisms are also referred to as *in vitro* reactions. With this mechanism, antibodies are present even in the absence of the drug.[65] These are true RBC antibodies and can be the cause of autoimmune hemolytic anemia. The laboratory and clinical findings may be indistinguishable from those found with idiopathic autoimmune hemolytic anemia. It is thought that drugs evoke the formation of these antibodies by having a direct effect on the immune system in a mechanism similar to microbial or viral infections.

Metabolic

Metabolic mechanisms of hemolytic anemia are considered to be oxidative. These most often occur in the presence of a glucose-6-phosphate dehydrogenase deficiency (G6PD deficiency). A G6PD deficiency is a disorder of the hexose monophosphate shunt, which is responsible for producing nicotinamide adenine dinucleotide phosphate hydrogen, or NADPH, in RBCs, which in turn keeps glutathione in a reduced state. Reduced glutathione is a substrate for glutathione peroxidase, an enzyme that removes peroxide from RBCs, thus protecting them from oxidative stress.[69] Without reduced glutathione, oxidative drugs can oxidize the sulfhydryl groups of hemoglobin, removing them prematurely from the circulation (ie, causing hemolysis).

Causative Agents

Over 130 drugs have indisputable evidence of causing hemolytic anemia. Since 2008, piperacillin is the most commonly reported agent.[60,63] A list of drugs associated with drug-induced immune hemolytic anemia is provided in Table e125-4. Of note, diclofenac, fludarabine, oxaliplatin, and cephalosporins are some of the most frequent offenders.[70] Of these, diclofenac is the most common, but can be especially prone to misdiagnosis.[68] Certain drugs and their responsible mechanisms are listed in Table e125-5. A list of agents associated with drug-induced metabolic hemolytic anemia is presented in Table e125-6.

Management of Toxicity

⑥ The treatment of drug-induced immune hemolytic anemia includes the immediate removal of the offending agent and supportive care. The severity of the reaction depends on the rate of hemolysis.

Immune

Immune hemolytic anemia caused by drugs through the hapten or adsorption and autoimmune mechanisms tends to be slower in onset and mild to moderate in severity. Conversely, hemolysis prompted through the immune complex mechanism (innocent bystander) can have a sudden onset, lead to severe hemolysis, and result in renal failure. In the metabolic mechanism, the degree of hemolysis depends on the severity of the enzyme deficiency and the amount of oxidative stress. However, the dose required for hemolysis to occur is often less than the prescribed quantities of the suspected drug.[69] Although severe hemolysis is rare, any drug that places oxidative stress on RBCs can cause drug-induced metabolic hemolytic anemia.

Glucocorticoids can be helpful in severe cases, but their use outside of autoimmune hemolytic anemia is not supported by strong evidence.[71] Other agents such as rituximab and IgG treatments have been used, but their role is yet to be clearly defined.[72-74] Patients experiencing hemolytic anemia from cephalosporins should be advised to avoid all agents in the class. Cross-reactivity may occur, and the second episode is likely to be worse than the first.[65]

Metabolic

⑥ Removal of the offending drug is the primary treatment for drug-induced metabolic hemolytic anemia. No other therapy is usually necessary because most cases are mild in severity. Patients with known G6PD enzyme deficiencies should be advised to avoid medications capable of inducing hemolysis.

DRUG-INDUCED MEGALOBLASTIC ANEMIA

In drug-induced megaloblastic anemia, the development of RBC precursors called megaloblasts in the bone marrow is abnormal. Deficiencies in either vitamin B_{12} or folate are responsible for the impaired proliferation and maturation of hematopoietic cells, resulting in cell arrest and subsequent sequestration. However, megaloblastosis can result from any interference with the synthesis of purines, pyrimidines, or protein.[75]

Diagnosis

Examination of peripheral blood shows an increase in the mean corpuscular hemoglobin concentration. Some patients can have a normal-appearing cell line, and the diagnosis must be made by measurement of vitamin B_{12} and folate concentrations. These megaloblastic changes are caused by the direct or indirect effects of the drug on DNA synthesis. The abnormality can be seen in any portion of the replication process, including DNA assembly, base precursor metabolism, or RNA synthesis.[75]

Causative Agents

Because of their pharmacologic action on DNA replication, the antimetabolite class of chemotherapeutic agents is most frequently associated with drug-induced megaloblastic anemia. Methotrexate, an irreversible inhibitor of dihydrofolate reductase, causes megaloblastic anemia in 3% to 9% of patients.[76] Other drugs, such as cotrimoxazole, phenytoin, and barbiturates, have also been implicated in megaloblastic anemia. Cotrimoxazole, at both low and high doses, can cause drug-induced megaloblastic anemia,[77,78] particularly in patients with a partial vitamin B_{12} or folate deficiency. Because the drug's affinity for human dihydrofolate reductase is low, patients with adequate stores of these vitamins are at low risk of developing drug-induced megaloblastic anemia. It has been postulated that phenytoin, primidone, and phenobarbital cause drug-induced megaloblastic anemia either by inhibiting folate absorption or by increasing folate catabolism. In both instances, the patient develops a relative folate deficiency. A list of drugs that have been implicated as causative factors in drug-induced megaloblastic anemia is given in Table e125-7.

Management of Toxicity

When drug-induced megaloblastic anemia occurs following chemotherapy, the anemia occurs rapidly, is considered an accepted ADR of therapy, and will resolve after removing the causative agent. If drug-induced megaloblastic anemia results from impairment of cellular availability or use of folic acid or vitamin B_{12}, supplementation with adequate amounts of these agents is indicated.[75] In cases of cotrimoxazole-induced megaloblastic anemia, a trial course of folinic acid, 5 to 10 mg up to four times a day, can correct the anemia.[77,78] Folic acid supplementation of 1 mg daily often corrects the drug-induced megaloblastic anemia produced by either phenytoin or phenobarbital, but some clinicians suggest that folic acid supplementation can decrease the effectiveness of these medications.[79]

DRUG-INDUCED THROMBOCYTOPENIA

Thrombocytopenia is usually defined as a platelet count below 100,000 cells/mm^3 (100 × 10^9/L) or greater than 50% reduction from baseline values.

Epidemiology

The annual incidence of drug-induced thrombocytopenia is about 10 cases per 1,000,000 population (excluding cases associated with heparin).[80] An increased incidence has been reported in older individuals, critically ill, and those exposed to sulfamethoxazole–trimethoprim, quinine, and GPIIb/IIIa inhibitors.[81] Although numerous epidemiologic studies have been reported, none of them have identified patient-specific risk factors that are associated with an increased risk for the development of drug-induced thrombocytopenia; however, a retrospective cohort analysis found that increased severity of thrombocytopenia was more likely in patients with sickle cell disease, malnutrition, infection, and tobacco, antibiotic, diuretic, or proton-pump inhibitor use.[82]

Heparin-induced thrombocytopenia has garnered much attention. Certain patient populations have a higher risk of developing HIT than others; patients older than 50 years and those who have had recent major cardiac or vascular surgery are the highest risk groups.[2,83] A lower risk is seen in patients receiving low-molecular-weight heparin (LMWH) (5/1,000) instead of unfractionated heparin (UFH) ((22/1,000).[83] Case-control and cohort analyses have found an increased burden of autoimmune disease and low albumin, respectively, among patients who develop HIT suggesting a possible link to increased risk in these populations. The most recent practice guidelines by the American Society of Hematology recommend varying degrees of platelet monitoring based on the relative risk of developing HIT.[84]

In 2020, the SARS-CoV2 epidemic revealed a HIT-like syndrome associated with both natural infection and immunization against the virus.[85,86] Positive platelet factor 4 (PF-4) antibodies were found in 6% to 12% of patients positive for SARS-CoV2 compared to 3% in the general population.[85,86] Vaccine-induced immune thrombotic thrombocytopenia (VITT) was established as a cause of cerebral venous thrombosis and other unusual thrombotic complications following vaccination against SARS-CoV2 and has a mechanism similar to HIT.[87] VITT is characterized by thrombosis, thrombocytopenia, and positive PF-4-heparin enzyme-linked immunoassay, or ELISA, and platelet activation assays.[87] Few patients with VITT have known risk factors for thrombosis. It is most frequently reported in women younger than 55 years within the first 16 days following vaccination with AZD1222 or Ad26.COV2.S vaccines, but has also rarely been reported in men, older individuals, up to 4 weeks after vaccination or following receipt of mRNA vaccines.[88]

Clinical Presentation

Drug-induced thrombocytopenia typically presents 1 to 2 weeks after a new drug is initiated, but may present immediately after a dose when an agent has been used intermittently in the past.[89] Rapid onset may also occur with the GPIIb/IIIa inhibitor class of drugs.[90] Development of thrombocytopenia may be associated with the systemic drug concentration, as is the case with linezolid.[91] This condition may be overlooked or misdiagnosed as idiopathic thrombocytopenic purpura (ITP); clinicians may distinguish between the two by the severity of thrombocytopenia (platelets <20,000 cells/mm^3 [20 ×10^9/L]), timing in relation to medication administration, and the presence of bleeding which almost always accompanies drug-induced thrombocytopenia.[90,92]

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia causes paradoxical increases in thrombotic rather than bleeding complications, with about 50% of patients with confirmed HIT developing thromboembolic complications.[93] It is caused by the development of antibodies against PF-4 and heparin complexes (Fig. e125-1).[93] Low-molecular-weight heparin binds less well to PF-4 than UFH, and therefore antibody formation is less common. However, antibodies developed by patients receiving UFH react against LMWH; thus, LMWH should not be used in patients with HIT.[83] After the antibodies bind to the complexes, platelet activation and aggregation occur, with subsequent release of more circulating PF-4 to interact with heparin. In addition, procoagulant microparticles are also released that increase the risk of thrombosis.[83]

FIGURE e125-1

Heparin-induced thrombocytopenia. Pathogenesis of HIT. IgG is the autoantibody against the heparin–PF4 complex. Platelets can bind to each other and become activated via the IgG–Fc receptor interaction, the PF4–PF4 receptor interaction, or both. Aggregation and thrombus formation may thus occur. Furthermore, IgG may bind to the endothelial cell–bound heparin–PF4 construct and cause vascular damage, which may also provoke thrombus formation. *(Reproduced, with permission, from Hammer GD, McPhee SJ. At least two types of HIT have been identified, spontaneous and delayed onset, but the true incidence has not been well established.[83] Patients with HIT type II usually present with a low platelet count (eg, below 150,000 cells/mm^3 [150 × 10^9/L]) or a 50% or more decrease in platelet count from the highest platelet count value after initiation of heparin, and thrombosis may be present at diagnosis.[93] The platelet count generally begins to decline 5 to 10 days after the start of heparin therapy. However, this decline can occur within hours of receiving heparin if the patient has received heparin (ie, within 100 days).[93] Major surgery can function as a reset for the window of developing HIT, and HIT may occur within 5 to 10 days after surgery despite previous exposures.[93] Thrombocytopenia and thrombosis can develop with low-dose heparin, heparin-coated catheters, or even heparin flushes.[93]

The diagnosis of HIT is made using a combination of clinical and laboratory assessments. Clinicians should use a scoring system, such as the 4T scoring system, to evaluate the probability of HIT.[93] Such a system should evaluate timing and magnitude of platelet drop, thrombosis, and other potential causes of thrombocytopenia.[93] If the scoring system indicates that HIT is possible or likely, the clinician should order laboratory tests, as HIT is difficult to exclude or confirm with only clinical information. Tests such as platelet activation assays, platelet aggregation studies, and enzyme-linked immunosorbent assay methods each have varying sensitivities and specificities and assist in the diagnosis of HIT.[7,10] Overall, these tests have a high negative predictive value.[93]

Protamine is an agent often used to neutralize heparin's anticoagulant action. Protamine-induced thrombocytopenia may be confused with HIT, since patients may have exposure to both agents. In protamine-induced thrombocytopenia, antibodies activate platelets similar to those in HIT, but it often occurs after cardiovascular surgery and is associated with earlier onset of thrombocytopenia and thrombosis, compared with the 5 to 10 day delay usually seen with HIT.[94]

Vaccine-Induced Thrombotic Thrombocytopenia

Vaccine-induced thrombotic thrombocytopenia (VITT) may also be confused with HIT. It may present with thrombotic complications or symptoms including headache, abdominal pain, nausea and vomiting, vision changes, shortness of breath, and/or leg swelling and pain.[88] It typically occurs within 4 to 20 days following vaccination, and patients may be critically ill before thrombocytopenia is discovered. Although the presentation may be confused with HIT, patients with VITT have not had prior exposure to heparin. If VITT is suspected, clinicians should use laboratory and imaging assessments to confirm the diagnosis. CBC with platelet count, D-dimer and fibrinogen assays, PF-4 antibody testing and imaging such as ultrasounds as needed to diagnosis thrombosis should be gathered for the initial work up. Patients with confirmed thrombosis or severe symptoms accompanied by thrombocytopenia and high D-dimers may be treated presumptively while awaiting confirmatory testing for PF-4 antibodies.

Mechanism

⑤ Drug-induced thrombocytopenia can result from immune-mediated mechanisms or through a nonimmune-mediated mechanism. Nonimmune-mediated mechanisms, such as direct-toxicity-type reactions, are associated with medications that cause bone marrow suppression. This results in suppressed thrombopoiesis and a decreased number of megakaryocytes. This type of reaction is dose dependent and often takes weeks to manifest.[90] Several mechanisms have been proposed for the development of immune-mediated drug-induced thrombocytopenia. These include hapten-type reactions, drug-dependent antibody mechanism, platelet-specific autoantibody, immune complex-induced thrombocytopenia, and drug-specific autoantibody type reaction. Although several mechanisms of drug-induced thrombocytopenia have been proposed, it is often not possible to determine the mechanism for an individual drug or patient, and more than one mechanism can be responsible for the condition.

Hapten-Type Reactions

In hapten-type reactions, the offending drug binds covalently to certain platelet glycoproteins (GP). Antibodies are generated that bind to these drug-bound GP epitopes. After the binding of antibodies to the platelet surface, lysis occurs through complement activation or through clearance from the circulation by macrophages.[95,96] Platelets are destroyed by the autoantibodies.[90] Hapten-mediated immune thrombocytopenia usually occurs at least 7 days after the initiation of the drug, although it can occur much sooner if the exposure is actually a reexposure to a previously administered drug.

Drug-Dependent Antibody

This mechanism is slightly different from the hapten-type mechanism. In this type of reaction, platelet-reactive antibodies bind platelets when the drug is present. The antibodies may occur naturally, but there is an increased affinity if the drug is present. Reactions typically occur after 5 to 10 days of therapy.[90] It is thought that antibodies exist within the patient's circulation that recognize an epitope on the platelet GP, but this recognition is too weak to result in antibody binding to the platelet surface. However, the drug contains structural elements that are noncovalently complementary to regions of the antibody and the GPs on the platelet surface. This causes an improved fit between the antibody and the platelet surface, with the drug "trapped" in-between, resulting in antibody binding of platelet.[95]

Eptifibatide and tirofiban are platelet GPIIb/IIIa receptor antagonists that prevent platelet activation and binding of fibrinogen, thereby inhibiting platelet thrombus formation. Competitive inhibition of fibrinogen binding causes platelet clearance and activation, so concomitant thrombosis may occur.[90] In clinical trials and postmarketing studies, about 0.1% to 2% of patients treated with these medications experience acute profound thrombocytopenia within several hours of their first exposure to the drug.[95-97] This acute drop in platelets without prior drug exposure suggested initially that this reaction was mediated by a nonimmune mechanism. However, a plausible immune-mediated mechanism has since been proposed. After binding to the GPIIb/IIIa receptor, these medications cause a conformational change in the receptor that allows it to be recognized by naturally occurring antibodies already in the patient's blood (ie, a ligand-induced binding site). In contrast to the two previously discussed immune-mediated mechanisms, the drug is not present within the binding between the antibody and the platelet surface. The drug has been removed from the platelet surface before the antibody binds, but the conformational change in the GPIIb/IIIa receptor remains.[96]

Abciximab, a GPIIb/IIIa receptor antagonist like tirofiban and eptifibatide, is also associated with thrombocytopenia. Abciximab-induced thrombocytopenia occurs through a different drug-specific antibody mechanism as opposed to a ligand-induced binding site mechanism with eptifibatide and tirofiban.[95-97] Abciximab is a chimeric monoclonal antibody. Therefore, it is not surprising that this molecule may exhibit some immunogenic properties. The murine component binds platelets' surface proteins and attracts antibodies that then destroy the platelet.[90] It has been demonstrated that patients who experience thrombocytopenia after the administration of abciximab have circulating antibodies that directly recognize the drug.[95,96] Because the drug is bound to platelets, thrombocytopenia results. About 2% of patients experience thrombocytopenia with the first administration and 10% to 12% with subsequent administrations.[98] Furthermore, in patients who experience the reaction with the first administration, some experience immediate thrombocytopenia, but a few patients develop delayed thrombocytopenia about 1 week after drug administration. In patients who experience immediate thrombocytopenia, drug-specific antibodies are naturally occurring and present at the time of drug administration. For those with a delayed response (6-8 days later), drug-specific antibodies are produced during this time, and because abciximab remains bound to platelets for up to 2 weeks, the reaction can still occur.[99] Since all three GPIIb/IIIa receptor antagonists are coadministered with heparin, it is important to distinguish between GPIIb/IIIa receptor antagonist-induced thrombocytopenia and HIT. A heparin-induced platelet aggregation study can help the clinician determine the offending agent. Pseudothrombocytopenia, defined as in vitro platelet aggregation in blood anticoagulated with ethylenediamine tetraacetic acid (EDTA), is clinically insignificant, but it must also be differentiated from thrombocytopenia induced by GPIIb/IIIa receptor antagonists.[100] This type of reaction may also occur with rituximab, and may be complicated by infusion reactions and disseminated intravascular coagulopathy (DIC).[90]

Platelet-Specific Autoantibody

In this type of reaction, a drug, such as gold or procainamide, induces the production of autoantibodies that bind to platelet membranes and cause destruction, but the causative drug does not have to be present for the reaction to occur. These autoantibodies can persist after discontinuation of the agent. Reports of thrombocytopenia up to 39 months after exposure have been published.[90] In contrast, the drug-dependent antibody reaction requires the presence of the drug to allow antibody binding.

Immune Complex

The final type of immune-mediated thrombocytopenia has been categorized as immune complex-induced thrombocytopenia.[95,96] This describes the mechanism of the most serious type of HIT, type II. HIT type II is less common but more severe than HIT type I and can be associated with more complications. In this type of reaction, heparin binds the platelet and forms an antigenic structure, which is then bound by antibodies. This complex activates the platelets.[93] HIT has been reported to occur in 1 of every 5,000 hospitalized patients and in 1% to 3% of patients after cardiac surgery. The risk is higher following major surgery than minor surgical procedures or medical treatment, and may be up to 10 times higher for those receiving UFH as compared to LMWH.[93]

A similar mechanism is seen in VITT, where vaccination leads to endogenous production of antibodies which cross-react to bind to PF-4 in the same manner as heparin.[88]

Causative Agents

The first systematic review of the literature and case reports associated with drug-induced thrombocytopenia were published in 1998.[101] At that time, 98 drugs were reported to be associated with thrombocytopenia. The Oklahoma group has continued to update this systematic review nearly every 2 years since 1998.[102] As of 2018, 339 drugs had been implicated in thousands of reports through 2014.[103] It has also been reported with foods, such as walnuts, cranberries, milk, and sesame seed.[104] The FAERS Public Dashboard reveals that reports of drug-induced thrombocytopenia have been increasing over the past 2 decades with 4,725 cases and 802 associated deaths in 2021.[105] One study found that only about 40% of implicated agents had a positive laboratory test, and only 10% should be considered definite causes.[90] This condition is more common in adults than children but may not be recognized in children. Thirty-one medications have been noted as definite or probable causes of thrombocytopenia in children.[92]

According to one analysis, carbamazepine, eptifibatide, ibuprofen, quinine, quinidine, oxaliplatin, rifampin, vancomycin, and sulfamethoxazole–trimethoprim are the agents most frequently associated with drug-induced thrombocytopenia.[81] The agents most commonly implicated in immune-mediated thrombocytopenia are quinine, quinidine, gold salts, sulfonamide antibiotics, rifampin, GPIIb/IIIa receptor antagonists, vancomycin, and heparin.[90,96] A list of medications (excluding cancer chemotherapeutic agents) associated with drug-induced thrombocytopenia is provided in Table e125-8.

Management of Toxicity

⑥ The primary treatment of drug-induced thrombocytopenia is immediate removal of the offending drug and symptomatic treatment of the patient. The use of corticosteroid therapy in the treatment of drug-induced thrombocytopenia is controversial, although some experts recommend it in severe cases.[106] Corticosteroids are sometimes helpful when clinicians are initially trying to distinguish between drug-induced thrombocytopenia and ITP. Clinicians may also consider the use of intravenous immunoglobulin, especially in severe illness, although data is limited.[90] Platelet transfusions may be used if severe bleeding is present.[90]

Heparin-Induced Thrombocytopenia

In the case of HIT, the main goal of management is to reduce the risk of thrombosis or thrombosis-associated complications in patients who have already developed a clot. All forms of heparin must be discontinued, including heparin flushes, and alternative anticoagulation must begin immediately.[93] Direct thrombin inhibitors are the traditional alternative; however, newer data increasingly supports use of fondaparinux and direct oral anticoagulants (DOACs) as viable options. A 2021 comprehensive systemic review and meta-analysis of 4,698 patients' data found similar safety and efficacy among multiple alternative agents, including argatroban, bivalidrudin, fondaparinux, DOACs, and danaparoid (not available in the United States).[107] The newest of the treatments, DOACs, are gaining popularity due to ease of oral administration strong safety and efficacy data and risk of rare fondaparinux cross-reactivity.[108]

Direct thrombin inhibitors are the alternative anticoagulants traditionally used in current practice. Four direct thrombin inhibitors are available in the United States: argatroban, bivalirudin, desirudin, and dabigatran, but only argatroban and bivalirudin are approved by the FDA for this indication.[93] Argatroban and bivalirudin are IV thrombin inhibitors. Argatroban is preferred for use in renal insufficiency,[83] is metabolized in the liver, and can be used in patients with end-stage renal disease. However, dosage adjustment is needed for patients with significant hepatic impairment. Bivalirudin is renally metabolized and requires dosage adjustments for patients with renal impairment. Because of this, it may be preferred in those with hepatic impairment. Both agents affect the partial thromboplastin time (PTT) and international normalized ratio (INR), so clinicians should follow labeled dosing protocols when transitioning patients to warfarin.[83,93] Time to therapeutic anticoagulation is faster with argatroban versus bivalirudin.[109] Safe and effective use of direct thrombin inhibitors may be limited by infrequent use, leading to their inappropriate dosing and monitoring, as well as misinterpretations of PTT due to the confounding effect of these agents.[10] Fondaparinux, an anticoagulant pentasaccharide that inhibits factor Xa, d, is not FDA-approved for treatment of HIT but is increasingly considered a primary treatment option.

The most recent guidelines by the American Society of Hematology include fondaparinux with argatroban, bivalirudin, danaparoid, and DOACs as possible treatment options with little evidence to suggest one over another.[84] Fondaparinux may also be considered when the patient is not in the intensive care unit due to ease of subcutaneous administration.[93] These agents should also be considered for the treatment of patients who have acute HIT without thrombosis because of the increased risk of thrombosis occurring in these patients. Subcutaneous dosage form may not result in cost savings as compared to DOACs. Although DOACs are not FDA-approved for treatment of HIT, they are increasingly being used in clinical practice. DOACs such as apixaban, dabigatran, edoxaban, and rivaroxaban do not react with PF4 or elicit recognition from HIT antibodies, which provides in vitro rationale for their use. Benefits of these agents include the oral dosage forms, rapid onset of action, and the ability to avoid long-term vitamin K antagonist therapy. Published case reports, case series, and prospective studies have evaluated DOAC use in HIT for over 4,500 person-days, and reported an incidence of recurrent thrombosis of 0.43/1,000 person-days. Most of the published data is for rivaroxaban. A 2021 review found that DOACs prevented thrombosis in 98%, while bleeding complications were only found in 3% of patients treated with them.[108] Although data is limited, preliminary evidence supports use of DOACs in the management of HIT. However, additional study is needed to determine their place in therapy and optimal duration of therapy.[10]

Thrombosis can occur in up to 50% of patients with HIT[83] and is often the precipitating factor that leads to the diagnosis. Because the high risk of thrombosis continues for days to weeks after heparin discontinuation and platelet recovery, continued anticoagulation with an alternative agent is essential during this time period.[93] Recovery begins within 1 to 2 days of discontinuation of the offending agent and is complete at 1 week. Antibodies to that agent may persist for years, so patients should be advised to avoid the drug indefinitely.[89] In cases where platelet recovery has not occurred after 5 days, some clinicians recommend considering intravenous immunoglobulin under the hypothesis that it may interrupt platelet activation and lead to more rapid recovery.[110,111] One analysis found similar outcomes between patients treated with intravenous immunoglobulin and therapeutic plasma exchanges, another immunomodulatory therapy posited to work by removing the antibody complexes.[112]

Vaccine-Induced Thrombotic Thrombocytopenia

Similar to that of severe HIT, treatment for VITT consists of non-heparin anticoagulation and may have more of a role for intravenous immunoglobulin. Platelet transfusion should be avoided in VITT in the absence of bleeding due to theoretical risk of thrombosis.[88] Steroids may be considered when platelet count is below 50,000/mm^3 [50 × 10^9/L].[113] Low fibrinogen levels are often associated with this condition and should not preclude use of anticoagulation.[88]

CONCLUSION

Drug-induced hematologic disorders are a heterogenous group of conditions which may cause mild to life-threatening illness. Numerous agents have been implicated as likely causing drug-induced hematologic disorders. Reports of these reactions have been increasing with many newly approved biologic and chemotherapeutic agents in use.

ABBREVIATIONS

ADR	adverse drug reaction
CFU	colony-forming unit
DAT	direct antiglobulin test
DIC	disseminated intravascular coagulopathy
DOAC	direct oral anticoagulant
ELISA	enzyme-linked immunoassay
FAERS	FDA Adverse Event Reporting System
Fc	crystalizable fragment (of immunoglobulin)
FDA	US Food and Drug Administration
G6PD	glucose-6-phosphate dehydrogenase
G-CSF	granulocyte colony-stimulating factor
GM-CSF	granulocyte-macrophage colony-stimulating factor
GP	glycoproteins
GPIIb/IIIa	glycoprotein IIb/IIIa
HIT	heparin-induced thrombocytopenia
HLA	human leukocyte antigen
HSCT	hematopoietic stem cell transplantation
IgG	immunoglobulin G
IgM	immunoglobulin M
ITP	idiopathic thrombocytopenic purpura
LMWH	intravenous immunoglobulin-weight heparin
MAA	moderate aplastic anemia
PF-4	platelet factor-4
RBC	red blood cell
SAA	severe aplastic anemia

UFH	unfractionated heparin
WBC	white blood cell
VITT	vaccine-induced thrombotic thrombocytopenia
VSAA	very severe aplastic anemia

SELF-ASSESSMENT QUESTIONS

1. The incidence of drug-induced hematologic diseases is best established by use of which method?
   - A. Meta-analyses
   - B. Phase II trials
   - C. Postmarketing surveillance
   - D. Randomized controlled trials
2. Initial management of suspected drug-induced thrombocytopenia should include which one as the first step?
   - A. Removal of the offending agent
   - B. Initiation of argatroban
   - C. Order for a stat CBC
   - D. Preparation for blood transfusion
3. When is it appropriate to rechallenge a patient with an agent suspected to cause drug-induced hematologic disease in order to confirm the diagnosis?
   - A. In stable patients
   - B. At the patient's request
   - C. When antibiotics are implicated
   - D. Rechallenges should be avoided
4. When evaluating drugs as a possible cause of drug-induced hematological disease, clinicians should use which approach?
   - A. Employ an ADR probability scale
   - B. Expect a definite diagnosis
   - C. Rely on laboratory data for confirmation
   - D. Rule out agents started in the distant past

5. Which is considered the *most* severe drug-induced hematologic disease?

    A. Agranulocytosis

    B. Aplastic anemia

    C. Hemolytic anemia

    D. Thrombocytopenia

6. When evaluating a patient for possible aplastic anemia, which of the following is the *most likely* cause?

    A. Acetaminophen

    B. Metformin

    C. Phenytoin

    D. Simvastatin

7. In patients with acquired aplastic anemia who are not candidates for HSCT, initial standard treatment includes:

    A. Cyclosporine monotherapy

    B. Cyclosporine and antithymocyte globulin

    C. Cyclosporine, antithymocyte globulin, and eltrombopag

    D. Eltrombopag monotherapy

8. The *most* commonly reported cause of drug-induced hemolytic anemia is

    A. Propylthiouracil.

    B. Phenytoin.

    C. Penicillin.

    D. Piperacillin.

9. HIT can be differentiated from VITT by

    A. Presence of bleeding.

    B. Presence of thrombosis.

    C. Prior heparin exposure.

    D. Presence of PF-4 antibodies.

10. Which of the following drugs is *most likely* to cause megaloblastic anemia?

    A. Methotrexate

    B. Metformin

    C. Clozapine

    D. Doxycycline

11. A patient with recent HIT presents with deep vein thrombosis in the left lower extremity. Initial outpatient treatment should include

    A. Argatroban.

    B. Apixiban.

    C. Enoxaparin.

    D. Warfarin.

12. Which of the following medications are most likely to be associated with direct toxicity on neutrophils, resulting in agranulocytosis?

    A. Penicillin

    B. Quinidine

    C. Sulfonamides

    D. Minocycline

13. Granulocyte colony-stimulating factor should be considered for use if a patient's neutrophil count, due to drug-induced agranulocytosis, falls below

    A. 5,000 cells/mm^3 (5 × 10^9/L)

    B. 500 cells/mm^3 (0.5 × 10^9/L)

    C. 1,000 cells/mm^3 (1 × 10^9/L)

    D. 100 cells/mm^3 (0.1 × 10^9/L)

14. Which test is *best* used to diagnose drug-induced hemolytic anemia?

    A. Hemoglobin

    B. Direct Coombs

    C. Reticulocyte count

    D. Red blood cell count

15. Treatment of drug-induced megaloblastic anemia should start with which of the following?

    A. Initiation of folinic acid

    B. Removal of the causative drug

    C. Initiation of vitamin B$_{12}$

    D. RBC transfusion

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Because the incidence of drug-induced hematologic disease is relatively rare, the use of postmarketing surveillance systems such as the FDA MedWatch program is necessary to establish credible reports from practice. (See the "Introduction" section and Key Concept 3 for more information on this concept.)

2. **A.** As with any drug-induced disease, the initial management includes removal of the suspected agent. Blood transfusion is not always necessary. Argatroban is only appropriate in heparin-induced thrombocytopenia (HIT). CBC may be rechecked, but should wait until after withdrawal of suspected agent. (See the Management of Toxicity portion of the "Heparin-Induced Thrombocytopenia" section and Key Concept 6 for more information on this concept.)

3. **D.** Rechallenging is not recommended due to the potential for life-threatening and/or dangerous complications. In vitro studies are often available to help determine causality. (See the "Introduction" section and Key Concept 4 for more information on this concept.)

4. **A.** Definitive diagnosis is difficult without a rechallenge. In the absence of a rechallenge, algorithms are useful to help determine the likelihood of an individual medication having caused the reaction. Laboratory data may be helpful but cannot always confirm diagnosis. (See the "Introduction" section for more information on this concept.)

5. **B.** Aplastic anemia is considered most severe, due to complications that can arise from the depletion of all blood cell lines. Rapid diagnosis and immediate treatment is crucial because of the high mortality rate. (See the "Drug-Induced Aplastic Anemia" section for more information on this concept.)

6. **C.** Cytotoxic agents such as antineoplastic therapy are well-known common causes; however, other agents such as phenytoin induce aplastic anemia through the production of a toxic metabolite. (See the Causative Agents portion of section "Drug-Induced Aplastic Anemia" for more information on this concept.)

7. **C.** The triple combination of cyclosporine, antithymocyte globulin, and eltrombopag has been more effective in achieving the best balance of outcomes and toxicity in adults with severe aplastic anemia, compared to other immunotherapy options. (See the Management of Toxicity portion of section "Drug-Induced Aplastic Anemia" for more information on this concept.)

8. **D.** While over 100 different medications have been linked to causing hemolytic anemia, the most commonly reported drug is piperacillin. (See the Causative Agents portion of section "Drug-Induced Hemolytic Anemia" for more information on this concept.)

9. **C.** Bleeding, thrombosis, and PF-4 antibodies may be present in both HIT and VITT. The syndromes are similar in presentation and distinguished only by prior exposure to heparin in HIT. (See the Epidemiology and Clinical Presentation portion of section "Drug-Induced Thrombocytopenia" for more information on this concept.)

10. **A.** The antimetabolite class is the most common cause of megaloblastic anemia due to their action on DNA replication. Methotrexate is associated with the development of megaloblastic anemia in up to 9% of patients. (See the Causative Agents portion of section "Drug-Induced Megaloblastic Anemia" for more information on this concept.)

11. **B.** DOACs, including apixaban, are a first-line option in patients with HIT who are not in the ICU setting. Argatroban would not be used in the outpatient setting due to its IV formulation. Enoxaparin should not be used in patients with HIT and warfarin should not be used in the initial treatment because it could worsen thrombosis. (See the Management of Toxicity portion of section "Heparin-Induced Thrombocytopenia" for more information on this concept.)

12. **C.** Sulfonamides are known to have direct toxicity to myeloid cells. Penicillin acts through the Hapten mechanism, quinidine through an immune-complex mechanism, and minocycline is not associated with agranulocytosis. (See Table e125-4 for more information on this concept.)

13. **D.** The use of growth-factors in the management of agranulocytosis is appropriate when the patient's neutrophils are less than 100 cells/mm^3 (0.1 × 10^9/L). This is considered standard of care among most clinicians. (See the Management of Toxicity portion of section "Drug-Induced Agranulocytosis" for more information on this concept.)

14. **B.** The Direct Coombs test identifies foreign immunoglobulins by combining a patients' RBCs with antiglobulin serum. It is the standard of practice for the diagnosis of drug-induced hemolytic anemia. The other choices here are not specific enough for a definitive diagnosis. (See the Diagnosis portion of section "Drug-Induced Hemolytic Anemia" for more information on this concept.)

15. **B.** As with all drug-induced hematologic diseases, removal of the causative agent is the first essential step, central to initial treatment. In addition,

for drug-induced megaloblastic anemia, the addition of folinic acid or vitamin B_{12} may be helpful to correct the anemia. (See the Management of Toxicity portion of section “Drug-Induced Megaloblastic Anemia” for more information on this concept.)

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter e126: Laboratory Tests to Direct Antimicrobial Pharmacotherapy

Jordan R. Smith; Brian J. Werth; Katie E. Barber

KEY CONCEPTS

KEY CONCEPTS

① Understanding the difference between normal host microbiota and typical pathogens will help determine whether a patient is truly infected or merely colonized.

② Direct examination of tissue and body fluids by Gram stain provides rapid information about the causative pathogen.

③ Isolation of the offending organism by culture or rapid diagnostic testing assists in the diagnosis of infection and allows for more definitive directed treatment.

④ Development of molecular testing systems (or rapid diagnostic testing) has improved our ability to diagnose infections and determine the antimicrobial susceptibilities for numerous pathogens, including fastidious or slow-growing mycobacteria and viruses.

⑤ *In vitro* antimicrobial susceptibility testing has limitations and often cannot truly mimic the conditions found at the site of an infection. This can cause discordance between *in vitro* susceptibility results and *in vivo* response to antimicrobial therapy.

⑥ Laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases.

⑦ When used appropriately, rapid automated susceptibility test systems appear to improve therapeutic outcomes of patients with infection, especially when they are linked with other clinical information systems.

⑧ Understanding the fundamentals of antimicrobial pharmacodynamic properties will help the clinician make drug selection and dosing decisions in situations where robust clinical data are lacking.

⑨ Routine monitoring of serum concentrations is currently used for a select few antimicrobials, eg, aminoglycosides and vancomycin, in an attempt to minimize toxicity and maximize efficacy.

⑩ Appropriate timing for the collection of serum samples when measuring antimicrobial serum concentrations is crucial to ensure that valid pharmacokinetic data are generated.

⑪ Monitoring of aminoglycoside serum concentrations and the use of extended-interval dosing can help maximize the probability of therapeutic success and minimize the probability of aminoglycoside-related toxicity for certain infections.

⑫ Vancomycin and aminoglycoside serum concentration monitoring should be routinely done to ensure adequate serum concentrations, minimize toxicity, and avoid the potential for resistance.

⑬ Antimicrobial pharmacodynamics has become a crucial consideration for the selection of both empirical and pathogen-directed therapy in the current era of antimicrobial resistance.

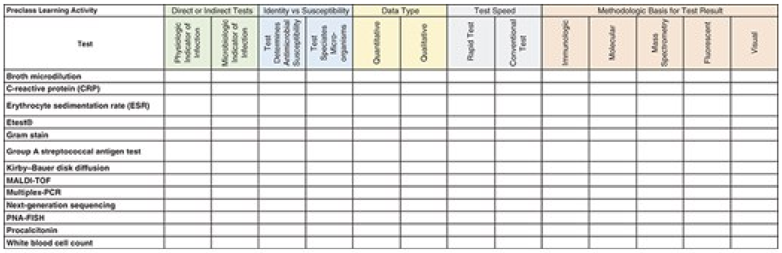
⑭ Optimization of antimicrobial pharmacodynamic parameters such as the ratio of the peak serum concentration to minimum inhibitory concentration (MIC) or the time that the antibiotic serum concentration remains above the MIC or the ratio of the area under the concentration-time curve to the MIC can improve infection treatment outcomes.

BEYOND THE BOOK

The goal of this learning activity is to begin thinking about the appropriate interpretation of various tests used to direct antimicrobial therapy. As you read through the chapter, work to complete this chart (**Fig. e126-1**) by indicating in each box whether the descriptors in each column apply to the test in each row.

FIGURE e126-1

Preclass learning activity.



Preclass Learning Activity	Direct or Indirect Tests		Identity vs Susceptibility		Data Type		Test Speed		Methodologic Basis for Test Result				
Test	Physiologic Indicator of Infection	Microbiologic Indicator of Infection	Test Determines Antimicrobial Susceptibility	Test Speciates Micro-organisms	Quantitative	Qualitative	Rapid Test	Conventional Test	Immunologic	Molecular	Mass Spectrometry	Fluorescent	Visual
Broth microdilution													
C-reactive protein (CRP)													
Erythrocyte sedimentation rate (ESR)													
Etest®													
Gram stain													
Group A streptococcal antigen test

INTRODUCTION

Selection of an appropriate antimicrobial regimen is a complex process involving knowledge of the infecting pathogen(s), the physiology of the patient, and the microbiological spectrum and pharmacokinetics and pharmacodynamics (PK/PD) of the anti-infective agent. A fundamental aspect of therapy is an appropriate diagnosis and identification of the pathogen. A vast array of laboratory tests, including rapid diagnostic technology, are available to assist in verifying the presence of infection, confirming the identity and susceptibility of a pathogen, and for monitoring the response to antimicrobial therapy. Organism susceptibility to the administered antimicrobials is key to determining the expected outcome from therapy, but *in vitro* susceptibility must be interpreted in the context of antimicrobial pharmacokinetic principles, since the drug must arrive at the site of infection in high enough concentrations and for long enough to exert its effect on the pathogen. Host characteristics such as immune dysfunction, infection site location, and body organ function all play a significant role in selecting the most appropriate antimicrobial for a given individual.[1] Many of the tests may be difficult to interpret correctly and therefore should be considered complementary to clinical judgment.

LABORATORY TESTS CONFIRMING THE PRESENCE OF INFECTION

Nonspecific Tests

Nonspecific tests of infection measure biomarkers that are typically abnormal in the infected patient but can also be abnormal in patients with noninfectious disorders. These are mostly biomarkers of inflammation, such as white blood cell (WBC) count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). Since these tests are nonspecific, it is important to interpret these results in the broader clinical context of the possibly infected patient.

White Blood Cell Count and Differential

Understanding the role of the WBC in fighting infection is important for diagnosis of infection, selection of drug therapy, and monitoring of patient progress. The major physiologic role of the WBC is to defend the body against invading organisms such as bacteria, viruses, and fungi. The normal range of the WBC count is 4,500 to 11,000 cells/mm^3 (4.5 × 10^9 - 11 × 10^9/L).[2] This range may vary among laboratories and patients, as it is dependent on factors like patient age, gender, or comorbidity status. WBCs usually are elevated in response to infection, but many other noninfectious conditions can increase the WBC count, including stress, rheumatoid arthritis, and leukemia. Pregnancy naturally increases WBC count, especially neutrophils. Certain drugs, eg, corticosteroids, can alter WBC count as well. Neutrophils are the most common type of WBCs in the blood, comprising approximately 70% of the total WBC count. In response to infection, they leave the bloodstream and enter the tissue to interact with and phagocytize offending pathogens. Mature neutrophils sometimes are referred to as segs because of their segmented nucleus, which usually consists of 2 to 5 lobes. Immature neutrophils lack this segmented feature and are referred to as bands. During an acute infection, immature neutrophils, or bands, are released from the bone marrow into the bloodstream at an increased rate, and the percentage of bands, which usuallyis about 5%, can increase relative to mature cells, or segs. The change in the ratio of mature to immature cells is often referred to as a “left shift” because of the way the cells used to be counted by hand with a microscope and charted from immature to mature cells from left to right.

Leukocytosis, an increase in WBCs, is a normal host response to infection. Although there are noninfectious causes of leukocytosis, and those causes must be acknowledged, most patients with bacterial infections will develop an elevated WBC count. This WBC count will almost always return to normal as the infection is treated. Combined with other factors suggesting infection, leukocytosis can be a powerful diagnostic and therapy-guiding tool. Neutropenia is often defined as an absolute neutrophil count of less than 500 cells/mm^3 (0.5 × 10^9/L) and is a common complication of cancer chemotherapy. Patients who are neutropenic are not only at a high risk for bacterial and fungal infections, but they are also incapable of increasing their WBCs in response to infection. The absence of leukocytosis also frequently can occur in the elderly and in severe cases of sepsis.[2,3]

Other Nonspecific Host Biomarkers of Infection

The inflammatory process initiated by an infection sets up a complex host response. Activation of the nuclear factor kappa B (NF-κB) transcription factors plays an important role in the regulation of the immune system. NF-κB is activated by bacterial and viral antigens, which eventually leads to the production of proinflammatory cytokines and chemokines. The rapid detection of activated NF-κB can be measured by transcription factor enzyme-linked immunosorbent assay (TF-ELISA) during a systemic inflammatory response syndrome (SIRS). This test may have some prognostic value in septic patients but it is uncommonly used clinically.

Acute-phase reactants, such as the ESR and CRP concentration, are elevated in the presence of an inflammatory process but do not confirm the presence of infection because they are often elevated in noninfectious conditions as well, such as collagen-vascular diseases and arthritis. However, large elevations in ESR and CRP are associated with infections such as endocarditis, osteomyelitis, and pyelonephritis.[4,5] ESR can be especially useful in tracking the improvement and resolution of chronic infections such as osteomyelitis, as it has demonstrable value in determining the efficacy of therapy.[6] CRP has a shorter half-life than ESR, normalizing within a week of resolution of tissue damage, and is therefore more useful in assessing response to therapy for acute infections. ESR can be affected not only by red blood cell count and shape, but also by fibrinogen and immunoglobulin production. Consequently, ESR should be interpreted cautiously in the setting of anemia (increased ESR) and polycythemia (decreased ESR), or in patients who receive intravenous immunoglobulin (IVIG; increased ESR).

In healthy individuals, procalcitonin (PCT) is produced by the thyroid during calcitonin synthesis, and only low levels are detected in the serum. However, during bacterial infection, PCT is produced through alternative pathways in diverse tissues including the spleen, kidneys, colon, brain, and lungs in response to inflammatory cytokines. PCT appears to be a more specific marker for bacterial infections than either CRP or ESR, and it can be a valuable tool for the clinician to help assess mortality risks of patients with infections and also can help determine when to initiate antibacterial therapy in respiratory tract infections.[7] PCT levels may help determine whether to discontinue empiric antibiotics in possibly infected patients as well as to determine when antibiotics can be discontinued in patients recovering from infections. In general, PCT levels below 0.25 ng/mL (mcg/L) are associated with low risk of infection and can help justify the discontinuation of antibiotics, while levels >0.5 ng/mL (mcg/L) may indicate that antibiotics should be continued. In patients with pneumonia or sepsis, it may be valuable to recheck a PCT level every 1 to 2 days to monitor resolution. If the PCT reduces by 80% to 90% or falls below 0.25 ng/mL (mcg/L), then it may be reasonable to discontinue antibiotics, assuming they do not continue to show other signs of infection such as hemodynamic instability or respiratory distress.[8]

Other Potentially Useful Biomarkers

Changes in endothelial membranes and the presence of a foreign pathogens and their endotoxins cause inflammatory cytokines, such as interleukin (IL)-1, IL-6, IL-8, and IL-10[9] and tumor necrosis factor alpha (TNF-α), to be produced by macrophages or lymphocytes.[10] Fluctuations in cytokine levels occur during an infection, which could be useful in staging and monitoring the response to therapy. Although abnormally high levels of TNF have been associated with a variety of noninfectious causes, spiked elevations in TNF are found in patients with serious infections, and there is a relationship between circulating cytokines and outcomes in patients with sepsis. Although the combination of elevations in endotoxin and individual cytokines has correlated well with the mortality rate, measurement of IL-6 was the most predictive of patient outcome.[10] Understanding the balance between these pro-inflammatory and anti-inflammatory processes likely will lead to interventions that can have a direct impact on the outcome of patients with sepsis.[11] Despite the growing evidence demonstrating the importance of cytokine biomarkers in predicting mortality in invasive infections, these are not routinely monitored and do not yet have a clear place in directing antimicrobial therapy.[12]

LABORATORY IDENTIFICATION OF PATHOGENS

Colonization versus Infection

① Pathogens are organisms that are capable of damaging host tissues and that elicit inflammatory host responses that produce the signs and symptoms of an infectious process. These organisms can be transferred from patient to patient, animal vector to patient, and environment to patient. They may even be opportunistic pathogens from the patient's own microbiome. Most organisms that make up the human microbiome occur naturally in the tissues of the host and provide myriad benefits, including defense by competing with would-be pathogens for essential nutrients, training and regulating the immune system, and synthesizing vitamins and liberating nutrients from our diets (**Table e126-1**).

TABLE e126-1

Examples of Normal Microbiota

	Gram-Positive		**Gram-Negative**		***Others***
	Cocci	***Rods***	***Cocci***	***Rods***	
Skin	*Staphylococcus* spp. (eg, *S. epidermidis), Streptococcus* spp.	*Corynebacterium* spp., *Propionibacterium* spp., Cutibacterium		Enteric bacilli (some sites), *Acinetobacter* spp. (Coccobacilli)	
Oropharynx	Streptococci—*Viridans* group *Micrococcus* spp.	*Corynebacterium* spp.	*Neisseria*	*Haemophilus* spp.	Spirochetes (non-pallidum *Treponema* spp.
GI tract	*Enterococcus* spp., *Peptostreptococcus* spp.	*Lactobacillus, Clostridium*		*Bacteroides* spp., Enteric bacilli (*E. coli, Klebsiella* spp.)	
Genital tract	*Streptococcus* spp., *Staphylococcus* spp.	*Lactobacillus, Corynebacterium* spp.		Enterobacteriaceae, *Prevotella* spp., *Candida* spp.	*Mycoplasma*

Organisms that comprise a healthy human microbiome can become pathogenic when host defenses become impaired or if the organisms are translocated to other body sites during trauma. The identification of an organism that is normal microbiota in a wound or otherwise sterile body cavity or fluid often becomes a dilemma for the clinician in deciding whether a patient is infected and requires treatment. Such is the case with *Staphylococcus epidermidis* when it is identified in the blood of a hospitalized patient. *S. epidermidis* is considered part of the normal skin microbiota and commonly colonizes IV catheters. When *S. epidermidis* is identified in the bloodstream, the patient's circumstances, eg, signs, symptoms, and laboratory indices supporting infection, as well as the probability of the organism being responsible for the infection, must be taken into account before determining whether the organism is causing disease. Additionally, the percentage of cultures from sterile sites that are positive for a typically commensal organism can help assess whether it's a true pathogen. For instance, growth of *S. epidermidis* in one of four blood culture samples may indicate contamination, while growth in four of four in combination with clinical symptoms may indicate true infection. Furthermore, the use of quantitative cultures or differential time-to-positivity of peripheral cultures and line cultures can be useful in implicating a line as a source. If the line cultures are positive for bacterial growth ≥2 hours before the peripheral cultures, then the line is likely the source of bacteremia.[13] Often the simple removal of the intravenous catheter can eliminate the organism from the bloodstream, thereby preventing unnecessary antibiotic use.[14]

Direct Examination

② Direct examination of infected tissue samples or body fluids can provide simple, rapid information to the clinician. The Gram stain is one of the first identification tests run on a specimen brought to the laboratory. Gram-positive cells have a thick peptidoglycan cell wall that retains crystal violet dye, and they appear purple after staining. Gram-negative cells have an additional lipopolysaccharide outer membrane over their peptidoglycan cell wall that retains safranin, and these bacteria appear pink after staining. Gram staining, in conjunction with microscopic examination of morphology, can provide a presumptive diagnosis and some indication of the organism's characteristics (Gram-positive, Gram-negative, Gram-variable, bacilli, or cocci).

Gram stains are performed routinely on cerebrospinal fluid (CSF) in cases of suspected meningitis, on urethral smears for venereal diseases, and on abscess or effusion specimens. In addition to being completed quickly, they are helpful in identifying organisms that may not grow easily in culture and which otherwise would be missed. Although Gram stains of sputum are performed routinely when respiratory tract infections are suspected, there is controversy regarding the usefulness of this test because the sputum is often contaminated or mixed with normal microbiota. If the sputum sample has a predominance of one particular organism in high numbers combined with the presence of many PMN granulocytes, and there are few squamous epithelial cells (<10 per low-power field), the diagnostic utility of the Gram stain is improved. **Figure e126-2** lists some common infecting pathogens grouped according to Gram stain and other characteristics.

Other staining techniques are used to identify pathogens such as those that are best identified microscopically because of their poor growth characteristics in the laboratory setting. Pertinent examples of these include the Ziehl–Neelsen and Kinyoun stains for acid-fast bacilli, which are used for identification of mycobacteria species as well as actinomycetes such as *Nocardia* spp. India ink, useful for identification of *Cryptococcus neoformans*, potassium hydroxide (KOH), useful for identification of *Candida* spp., and Giemsa stains, useful for identification of *Plasmodium falciparum, Treponema pallidum, Histoplasma, Pneumocystis, Toxoplasma*, and *Leishmania*, are other important examples.[15]

Cultures

3 Isolation of the etiologic agent by culture is the most definitive method available for the diagnosis and eventual treatment of infection. Although suspicion of a specific pathogen or group of pathogens is helpful to the laboratory for the selection of a specific cultivating medium, the more common procedure for the laboratory is to screen for the presence of any potential pathogen. After receipt of a clinical specimen, the laboratory will inoculate the specimen in a variety of culture media. Some culture media are designed to differentiate various organisms on the basis of biochemical characteristics or to select specific organisms on the basis of resistance to certain antimicrobials. Other media are used commonly for the isolation of more fastidious organisms, such as *Listeria, Legionella, Mycobacterium,* or *Chlamydia*. Cultures for viruses are more difficult to perform and are undertaken primarily by larger institutions or outside laboratories because of the technical expense and time involved in processing samples.

When a culture is obtained, careful attention must be paid to ensuring that specimens are collected and transported appropriately to the laboratory. Every effort should be made to avoid contamination with normal microbiota and to ensure that the specimen is placed in the appropriate transport medium. Culture specimens should be transported to the laboratory as soon as possible because organisms can perish from prolonged exposure to air or drying. This is especially important for swab specimen preparations. Some transport media may not be ideal for all organisms. Specimens that contain fastidious organisms or anaerobes require special transport media and should be forwarded immediately to the laboratory for processing. Finally, the source of the specimen should be clearly recorded and forwarded along with the culture to the laboratory. This process will aid the laboratory in differentiating true pathogens from the expected normal microbiota, and it will help in the selection of the appropriate culture media. Detection of microorganisms in the bloodstream by standard culturing techniques is difficult because of the inherently low yield of organisms diluted by blood, humoral factors with bactericidal activity, and the potential of antimicrobial pretreatment affecting organism growth. Most blood collection bottles dilute the blood specimen 1:10 with growth medium to neutralize the bactericidal properties of blood as well as any circulating antimicrobials. The addition of a polyanionic anticoagulant abolishes the effect of complement and antiphagocytic activity in the specimen. Some laboratories also add β-lactamase to their blood collection bottles to inactivate antibiotics such as penicillins or cephalosporins. Some culture bottles may also contain a suspension of activated charcoal which can help adsorb antimicrobials in the sample, thereby increasing the chances that the organism will grow.

The initial identity of the organism can be determined by a variety of testing procedures. General schemes differentiate organisms into primary groups, such as Gram-positive and Gram-negative, and aerobic and anaerobic. This can be accomplished by simple Gram staining, as described previously, by evaluating organism growth patterns on selective media or incubation conditions, and by testing for the presence or absence of specific enzymes and chemical characteristics, such as hemolytic and fermentation properties. This preliminary information, which is readily obtainable from the laboratory, can greatly assist the clinician in choosing the appropriate empirical therapy. Historically, definitive identification of organisms has required multistep testing procedures in order to deduce an organism's identity on the basis of specific biochemical properties. However, increasingly, rapid diagnostic technologies such as matrix-assisted laser/desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) and self-contained, direct-from-culture molecular probe and multiplex PCR systems (eg, Verigene® Nanosphere, Biofire® Filmarray®) are providing faster and more definitive pathogen identification than traditional biochemical methods. These are described in more detail in the coming sections.

The use of automated culturing systems has reduced the time it takes to identify growth in culture bottles from days to hours. One commonly used system is the BACTEC™ system, which uses bottles of growth medium containing a fluorescent sensor that monitors culture bottles every 10 minutes for the presence of carbon dioxide (CO_2) as a by-product of microorganism growth. Computers monitoring the system alert laboratory personnel of positive culture results by both audible and visual alarms. Once detected, a battery of testing can be performed rapidly, which shortens the reporting time and enables clinicians to obtain preliminary information about the organism to guide antimicrobial therapy. Commercially available automated systems can inoculate the test organism into a series of panels containing a variety of test media, sugars, and other reagents. The system can then photometrically determine the results and compare the findings to a library of organism characteristics to produce a definitive identification.[15]

Viruses can be detected by direct observation of inoculated culture cells for cytopathic effects or by detection of antigens after incubation by immunofluorescence methods. The culture method is most useful for organisms such as cytomegalovirus (CMV) or *Herpes simplex* virus because these viral agents are rapidly propagated in culture cells, making them easily detected.[16]

Rapid Diagnostic Technologies

There are now many FDA-approved rapid diagnostic testing methodologies for infectious diseases. In the current era of managed care and antimicrobial stewardship programs, rapid diagnostic tests (RDTs) are critical. The need for RDTs is further highlighted by the emergence of multidrug-resistant bacteria and increased pathogen virulence. A major focus of RDT is pathogens associated with increased morbidity and mortality, which include influenza virus, methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* spp. (VRE), *Clostridioides difficile*, extended-spectrum β-lactamase (ESBL)– and carbapenemase-producing Enterobacteriaceae, and *Mycobacterium tuberculosis*.

The benefit of rapid diagnostic technology is to quickly identify and/or rule out infectious pathogens, streamline antimicrobial therapy, and improve infection control measures such as isolation. Rapid diagnostics can significantly reduce the time to pathogen identification and susceptibility, thus improving the clinician's ability to optimize therapy. Pathogen RDT also prompts de-escalation or potential discontinuation of antimicrobial therapy, which decreases the potential for antimicrobial resistance.

The process of RDT often requires the evaluation of a clinical specimen such as blood, stool, or bodily fluids. These specimens are processed in a qualitative or quantitative manner to provide a result that is available within 15 minutes to a few hours (depending on the technology). This contrasts with traditional culture methodologies discussed above which may take 2 to 4 days, eg, for *Staphylococcus* spp. in the blood, or up to 6 weeks, as in the case of slow-growing *Mycobacterium* spp. The most current RDT modalities are based on immunologic assays, molecular techniques, and mass spectrometry.

DIAGNOSIS OF INFECTION USING IMMUNOLOGIC ASSAYS

④ Immunologic methods for the diagnosis and monitoring of infection have become indispensable laboratory tools. Immunologic assays use reporter linked antibodies that selectively bind pathogen-specific antigens or resistance determinants in clinical samples in order to identify pathogens and/or susceptibility phenotypes. These methods have the advantage of a rapid turnaround time and a high level of sensitivity and specificity. Some rapid antigen detection tests (eg, identification of group A streptococci and the rapid influenza diagnostic tests) are simple to use, can be performed conveniently in a pharmacy or physician's office, and can be an important part of the decision whether to administer antimicrobials for a suspected infection. One limitation of these assays is that patients may test positive for these antigens even if they have already recovered from an infection. In addition, the positive test result indicating the presence of the potential pathogen does not determine whether the patient was infected or simply colonized with the organism.

Antibody-antigen detection can be accomplished by a variety of reporter systems. Immunofluorescence is used routinely for the detection of CMV, respiratory syncytial virus, varicella-zoster virus, *Treponema pallidum* (syphilis), *Borrelia burgdorferi* (Lyme disease), and *Chlamydia trachomatis*. Latex agglutination is useful for detecting meningococcal capsular antigens in CSF of patients suspected of having bacterial meningitis, in the diagnosis of *Legionella pneumophila*, and to detect penicillin-binding protein 2a (PBP2a), which mediates β-lactam resistance in methicillin-resistant staphylococci. Enzyme-linked immunosorbent assay (ELISA) is a commonly employed method for detecting HIV, herpes simplex virus, respiratory syncytial virus, pneumococcal serum antibody, *Neisseria gonorrhoeae*, and *Helicobacter pylori*.[16]

Molecular Techniques for the Detection of Microorganisms

Nucleic Acid Amplification Methods

Nucleic acid amplification methods are now considered a standard laboratory tool and are increasingly important in situations in which rapid turnaround time is essential to improve patient diagnosis and outcome. Examples include real-time universal screening for acute HIV infection and routine testing and monitoring of patients receiving treatment for HIV infection, as well as the isolation and detection of fastidious or slow-growing organisms such as *M. tuberculosis*, *B. burgdorferi*, and *H. pylori*.[17,18] These highly sensitive methods can detect and quantify minute amounts of target nucleic acid in a rapid manner. The polymerase chain reaction (PCR) is based on the capability of a DNA polymerase to copy and elongate a targeted sequence of DNA. Each cycle doubles the number of copies of the targeted DNA sequence present at the start of the cycle, thereby exponentially increasing the overall number of DNA copies. In theory, more than 1 million copies of the original sequence can be generated from a single copy in as few as 20 cycles. Although this amplification technique is sensitive and has wide-reaching applications, it is not without problems. The powerful amplification procedure can yield false-positive results when samples are contaminated by nucleic acid left over from previously amplified DNA or by dead pathogens that exist in the sample. Furthermore, it cannot discriminate colonization from infection.

Advancement in molecular genetics techniques has replaced labor-intensive multistep methods with rapid kits capable of identifying a variety of important genetic biomarkers with high sensitivity and specificity and minimal technologist intervention. These advancements include the use of multiple sets of amplification primers, known as multiplex PCR, incorporation of fluorescent reporters for instantaneous detection and quantification of amplified products, known as real-time PCR, and PCR amplification of RNA by converting target RNA sequences with reverse transcriptase to complementary DNA templates prior to amplification. The integration of nucleic acid extraction, multiplex amplification, and real-time detection into a single closed-system capable of handling minimally processed clinical samples has revolutionized modern laboratory practice. Syndrome-specific multiplex panels, eg, Biofire® Filmarray®, are less labor-intensive, yield a faster turnaround time, reduce the likelihood of contamination, and can be more cost-effective than conventional methods.[19]

Real-time detection of amplified nucleic acid targets in many systems relies on nonspecific fluorescent reporters but DNA microarrays are another option. Microarrays are grids of short sections of DNA that are complementary to a target sequence. Binding of these oligonucleotide probes triggers a colorimetric (based on silver or gold), fluorescence, or chemiluminescence reporter, allowing for quantification of the target sequence. These microarray systems can also be adapted to detect specific proteins. Peptide nucleic acid fluorescence in situ hybridization (PNA-FISH) uses fluorescent-labeled nucleic acid probes to target ribosomal RNA sequences.[20,21] These rRNA sequences are specific to different species of microorganisms. This assay has fallen out of favor and largely been replaced by more efficient hybridization probes, MALDI-TOF MS, and next-generation sequencing.

Mass Spectrometry to Detect Microorganisms

Mass spectrometry is another useful diagnostic technology that can identify microorganisms more rapidly than conventional methods but also with greater accuracy most of species.[22] This technology vaporizes bacterial samples with a laser, ionizing proteins and other macromolecules. The resulting cloud of ionized analytes are then separated by mass and charge which influence the time of flight to a detector. The resulting spectrum is a sort of fingerprint for an organism that is matched to a database of known species of microorganisms to determine its identity. MALDI-TOF MS has become the primary method for speciating microorganisms in clinical labs that have access to one. The large library of species and the specificity of this system has led to the routine identification of organisms that would not otherwise be speciated by conventional methods. This has led to the recognition of certain pathogens that have been discounted, underappreciated, or completely unrecognized in the past. MALDI-TOF MS systems can identify microorganisms from a single colony of growth in minutes resulting in reliable speciation an average of 1.5 days earlier than conventional methods and can save hundreds of thousands of dollars in reagents and labor in the clinical lab, not to mention the benefits to patient care. When MALDI-TOF MS is integrated into antimicrobial stewardship programs it is the most cost-effective rapid diagnostic, leading to approximately $30,000 savings per quality-adjusted life-year in patients with bacteremia and preventing 1 out of every 14 deaths.[23] Many experts believe that the full potential of MALDI-TOF MS to direct antimicrobial therapy has not yet been realized. Direct-from-culture bottle methods reduce the time to speciation by 12 to 48 hours, depending on the organism, and there is potential for MALDI-TOF MS spectra to be used to identify certain types of antimicrobial resistance in addition to speciation.[24] Earlier speciation and susceptibility determination can mean fewer days of ineffective or unnecessary antimicrobial therapy.

Next-Generation Sequencing to Identify Microorganisms

Next-generation sequencing (NGS) is a technique that allows for rapid genomic sequencing of microorganisms. This approach does not require targeted primers or prior knowledge of the most likely pathogens to encounter in a sample, can be performed directly from clinical samples, and can identify all organisms present in a sample without prior isolation or culture. Consequently, NGS is the most comprehensive and reliable method for speciation of microorganisms and can be especially useful for fastidious organisms. Many times, clinical laboratories will use this technology to sequence species-specific variable DNA regions such as the 16S-24S rRNA to differentiate organisms, but whole-genome sequencing can also be performed. Consequently, in addition to speciation, NGS can be useful to detect novel resistance variants or to track outbreaks. Similar to other molecular methods, the presence of microorganism DNA in a clinical sample does not differentiate infection from colonization or contamination. Whole genome sequencing has demonstrated excellent concordance with MALDI-TOF in bacterial identification, and it also has demonstrated concordance with standard susceptibility testing methods for determining bacterial antibiotic susceptibilities.[24] However, while sequencing technology has become much faster and more affordable in recent years, cost, data processing skills, and turnaround time for NGS are inferior to other molecular tests and MALDI-TOF, so NGS is generally used as a secondary method when other techniques fail. In the future NGS could become a universal method for rapid speciation and susceptibility determination while providing rich data for tracking clonal transmission.[25,26]

EVALUATION OF ANTIMICROBIAL ACTIVITY AND DETERMINATION OF ANTIMICROBIAL PHARMACODYNAMICS

⑤ ⑥ The laboratory evaluation of antimicrobial activity is an important component of the pharmacotherapeutic management of infectious diseases. The integration of this activity with various pharmacokinetic properties of the antimicrobial agent determines the drug's pharmacodynamic characteristics. Antimicrobial pharmacodynamics has become a crucial consideration for the clinician in selecting appropriate therapy, formulary decision making, and developing antimicrobial stewardship protocols.

⑤ Most antimicrobial susceptibility testing methods that are used in the clinical laboratory are well characterized and have been standardized by the Clinical and Laboratory Standards Institute (CLSI).[27] However, controversies exist about which testing method provides the most useful information, how to best report these results to clinicians, and how to apply them to the treatment of patients.[28]

Most of the standardized and well-accepted susceptibility testing methods evaluate the MIC of aerobic, non-fastidious bacteria. However, substantial progress has been made to develop sensitive, specific, reproducible, and clinically useful susceptibility tests for anaerobic bacteria, fungi, mycobacteria, and viruses. Continued advances in technology should further improve testing methods and the speed with which the results can be applied to the management of patients. Although these newer systems are often expensive, the increased quality and decreased overall costs of patient care can improve their cost-effectiveness. Susceptibility testing methods available in the clinical laboratory can be qualitative (eg, disk diffusion), semi-quantitative (eg, MIC testing), or deductive (eg, molecular, immunologic, or chromogenic screening) in nature.

QUALITATIVE ANTIMICROBIAL SUSCEPTIBILITY TEST METHODS

Disk Diffusion Assay

The disk diffusion assay method for susceptibility testing (Kirby–Bauer method) was developed to reduce the labor needed for tube dilution susceptibility testing.[29] It still is used in many clinical microbiology laboratories owing to its high degree of standardization, reliability, flexibility, low cost, and simplicity of test interpretation. Up to 12 user-selected antibiotic-impregnated paper disks are placed on an agar plate previously streaked with a standard suspension of bacteria (1×10^8 to 2×10^8 CFU/mL [1×10^{11} - 2×10^{11} CFU/L]). The drug contained in the disk diffuses in a concentration gradient out into the agar. The plate is incubated for 16 to 24 hours at 35°C to 37°C, and visual bacterial growth occurs only in areas in which the drug concentrations are below those required for growth inhibition. The diameters of the zones of inhibition are measured via calipers or automated scanners and are compared with standard zone size ranges that determine susceptibility, intermediate susceptibility, or resistance to the antimicrobials tested (Fig. e126-3).

FIGURE e126-3

Disk diffusion susceptibility test. Antibiotic-impregnated disks are placed on the surface of a plate previously inoculated with the test organism. The plate is incubated for 18 hours, and the subsequent zones of inhibition are measured. The zone size correlates with the sensitivity of the organism. The larger the zone, the more sensitive is the organism to the specific antibiotic. On the basis of predetermined zone breakpoints, organisms can be classified as susceptible, resistant, or intermediately susceptible to the antibiotic. *(Photograph reprinted with permission from the Anti-Infective Research Laboratory, Wayne State University, Detroit, MI.)*

Although factors such as agar composition, incubation temperature, bacterial inoculum, and antibiotic paper disk composition can influence results, the standards for testing conditions and interpretive zone sizes are well defined by the CLSI. In some laboratories disk diffusion tests are performed with nonstandard inocula directly from positive culture bottles. The sensitivities may not be fully reported, but they result a day before other methods and can be a useful way to screen for multiple organisms or colony types with different susceptibility patterns for further workup.

SEMI-QUANTITATIVE ANTIMICROBIAL SUSCEPTIBILITY TESTING

Minimum Inhibitory Concentrations

5 The minimum inhibitory concentration (MIC) is defined as the lowest antimicrobial concentration that prevents visible growth of a standard inoculum of organism after approximately 24 hours of incubation under standardized growth conditions. The MIC semi-quantitatively determines *in vitro* antibacterial activity. The MIC test is "semi-quantitative" because it allows detection of inhibitory concentrations based on doubling of antibiotic, and as such there is no ability to determine an exact concentration required to inhibit bacterial growth. MICs were traditionally determined through the micro or macro dilution methods, which use liquid growth medium (broth), doubling serial dilutions of antimicrobials in test tubes or microtiter wells, and a standard inoculum of bacteria (approximately $10^{5.5}$ to 10^6 colony-forming units [CFU]/mL [$10^{8.5}$ - 10^9 CFU/L]). The organism, broth, and antibiotic are incubated at 35°C to 37°C (95°F-98.6°F) for 16 to 24 hours for most organisms and drugs and then examined for visible bacterial growth (**Fig. e122-4**). Using these methods, the MIC can be determined manually by a technician, or by an automated system. The other two methods for MIC determination are the gradient strip method and new morphokinetic cellular analytical systems.

FIGURE e126-4

Macrotube minimum inhibitory concentration (MIC) determination. The growth control (*C*), 0.5 mg/L, and 1 mg/L tubes are visibly turbid, indicating bacterial growth. The MIC is read as the first clear test tube (2 mg/L).

Automated Antimicrobial Susceptibility Testing

The microdilution MIC testing method is the most commonly used susceptibility testing method in the clinical microbiology laboratory and the method used by automated systems (**Fig. e122-5**). Various degrees of automation have been applied to susceptibility testing. Early advances included automated preparation of microtiter trays, instrument-assisted readers, and computer-assisted result databases. These systems often incorporate microprocessors, robotics, and microcomputers to rapidly identify organisms and produce susceptibility test results in as few as 3 hours. These systems have limitations in the numbers and types of antimicrobials to use in the test, especially with premade or premanufactured trays, and a limited ability to detect some forms of antimicrobial resistance (eg, β-lactamases in gram-negative bacteria). There are three rapid automated susceptibility test systems in common use in clinical microbiology laboratories. The Vitek system uses small plastic reagent "cards" that contain 64 microwells for the testing of various antimicrobials or indicator chemicals. Bacterial test suspensions enter the wells by capillary diffusion, and growth is monitored automatically via photometric assessment of turbidity every hour for up to 15 hours. When the growth control reaches a specified turbidity level, growth curves for all wells are calculated and compared with the growth control curve for slope normalization. Computerized linear regression and the use of best-fit line coefficients produce an algorithm-derived MIC. The clinical laboratory can control whether the output that is generated contains qualitative susceptibility, quantitative susceptibility, or both.

FIGURE e126-5

Depiction of a 96-well microtiter plate with minimum inhibitory concentration (MIC) assays for antibiotics used commonly against gram-negative pathogens. The shaded wells indicate visible bacterial growth. The MICs (milligrams per liter) for this organism would be 16 for piperacillin, 4 for aztreonam, 2 for ceftazidime and cefepime, 1 for meropenem, 0.5 for ciprofloxacin and gentamicin, and 0.25 for tobramycin. GC is the growth control (no antibiotic added).

The MicroScan WalkAway system is a rapid test system that uses fluorogenic substrate hydrolysis as an indicator of bacterial growth. This system uses standard micro-dilution test trays and a computer-controlled incubator and reader unit that can perform robotic manipulations, such as reagent addition and tray rotation, to allow for spectrophotometric or fluorometric growth assessments. As with the Vitek system, growth curves are generated, and algorithms applied for the determination of MICs; output is via computer or video display.

The final system is the BD Phoenix Automated Microbiology System. This system uses an oxidation–reduction detector and a turbidimetric growth detection system to determine antibiotic resistance/susceptibility. Output of data is similar to the other two automated systems previously described.

The results obtained from all three systems generally are comparable, meaning reproducibly within one doubling dilution of each other. However, there have been documented differences in the ability of these systems to accurately detect emerging resistance mechanisms such as staphylococci with reduced susceptibility to vancomycin and carbapenem resistance in gram-negative pathogens.[30,31] Importantly, all of the systems contain information management software that allow for the storage and rapid retrieval of historical susceptibility data. They can produce patient data reports, antibiograms (summaries of overall resistance for organisms causing infections in a given hospital), and epidemiologic reports. These systems also can be interfaced with other clinical information systems, such as the pharmacy, infection control, or other laboratory data systems, which can help direct antimicrobial stewardship policies and interventions to improve clinical outcomes.[32]

OTHER SUSCEPTIBILITY TESTS

Gradient Strip Tests

⑦ The Epsilometer test (Etest) and related gradient strip tests combine the benefits of quantitative MIC test methods with the ease of agar diffusion testing. The Etest is a plastic strip impregnated with a known, prefixed concentration gradient of antibiotic that is placed on an agar plate streaked with a suspension of known bacterial inoculum. The drug rapidly diffuses from the plastic strip to form a concentration gradient within the agar. After overnight incubation, elliptical zones of inhibition are formed; the point where the bottom of the ellipse crosses the plastic strip is correlated with an MIC value printed on the strip (**Fig. e122-6**). Similar products such as the M.I.C. Evaluator™ and the Liofilchem® MIC Test Strips are also available and differential performance characteristics are being evaluated.[33] Many investigators have analyzed the Etest's correlation with standard susceptibility methods and assessed its potential clinical use. In general, values obtained with Etest methods are comparable with or even more consistent and accurate than standard methods.[34] The widespread clinical use of the Etest has been limited primarily by the higher costs of the test strips (nearly 10 times costlier than antibiotic-impregnated disks) in relation to the benefits that may be gained from their use. However, many clinical laboratories use Etests for new antibiotics for which they may lack other means of susceptibility testing or for agents that may not be in their standard panels for automated susceptibility testing. Although their use is not as widespread as other means, they can potentially provide important information for clinical decisions.

Morphokinetic Cellular Analysis

The newest and fastest method for determining MIC is morphokinetic cellular analysis (MCA). MCA is a microscopy-based platform that allows for automated single-cell growth analysis at 10-minute intervals of cells exposed to different concentrations of antimicrobials. MCA can yield an MIC result in approximately 7 hours directly from a positive culture bottle, much faster than conventional methods. This turnaround time is slower than many current molecular systems but can detect mechanisms of resistance that we cannot yet screen for genetically. Like many other automated systems, MCA susceptibility systems such as the Accelerate PhenoTest™ BC Kit are equipped with a fluorescence-based molecular hybridization system (FISH) for rapid pathogen identification in approximately 90 minutes.[35,36] Similar to MCA, resonant mass measurement-based MIC testing systems, which weigh individual organisms over time, may provide even shorter turnaround time in the future.

Limitations and Problems with MIC Testing

⑤ Some of the limitations and problems of MIC testing have important implications for the management of patients with serious infections. For example, because the MIC only represents the concentration of antimicrobial that is needed to inhibit visual growth of the most resistant cells within the tested bacterial population, there can be a small percentage of bacteria present within the large numbers at the site of infection that are more antimicrobial-resistant than the MIC would indicate. Therefore, the standard bacterial density used to perform the susceptibility testing (eg, $10^{5.5}$ CFU/mL [$10^{8.5}$ CFU/L]) may overestimate the antimicrobial's actual activity at the site of infection, where bacterial densities can be orders of magnitude higher for certain infections. Use of the antimicrobial then could select for these more resistant subpopulations, resulting in poor clinical response. This phenomenon can be observed with intermediate vancomycin resistance in *S. aureus*, as well as in strains of gram-negative bacteria that produce inducible β-lactamases.[37]

Many other factors can also influence the *in vitro* MIC value obtained and its subsequent application to a clinical situation. Factors such as the choice of bacterial growth medium, the cation content of the medium, and the presence or absence of protein in the medium can affect the activity of a few drugs significantly. MIC values of antibiotics that are highly bound to plasma proteins are significantly higher when the test medium contains human serum. As testing of these drugs in a serum-supplemented medium has not gained widespread acceptance, their clinical activity may be overestimated by *in vitro* MIC test results. Fortunately, the standardized guidelines for testing and quality assurance procedures proposed by the CLSI attempt to minimize the impact of these problems and are followed by most clinical and research laboratories.[27] However, when a patient infected with an apparently susceptible organism fails therapy, it is important for the clinician to consider these potential confounding factors as possibly being related to the observed failure. In such situations, consideration of antimicrobial pharmacokinetics and pharmacodynamics can help better predict therapeutic response as compared with organism susceptibility alone.

Qualitative versus Quantitative Susceptibility Testing of Microorganisms

Quantitative MIC data often are reported to the clinician qualitatively by deeming an organism "susceptible" (S) or "resistant" (R). Organisms can also be labeled "intermediate" (I) or "susceptible-dose-dependent" (S-DD) if those criteria are applicable for the organism and agent. The S-DD label indicates that for some drugs and pathogens successful treatment may be possible with PK-PD optimized regimens. Many factors are considered to determine these qualitative susceptibility classifications, also referred to as "breakpoints" for the antibiotic. These include pharmacokinetic properties of the drug, the epidemiological distribution of MICs for the organism(s), and the clinical and microbiologic responses observed for the antimicrobial against strains of bacteria with various MIC values. The derived breakpoints make the susceptibility data easier to interpret for clinicians. Pathogens classified as susceptible to an antibiotic are those that fall below a breakpoint MIC or zone size, and these breakpoint values have considered clinically achievable, safe serum concentrations in a patient as well as killing activity of the antimicrobial agent. Conversely, resistant organisms are bacteria that tend to have higher MICs and, when treated with the antimicrobial, are likely to result in a suboptimal clinical response, even at the highest doses. The intermediate classification exists when the number of strains with MICs in the given range is too small to derive robust conclusions on susceptibility or resistance to the antimicrobial. Responses to therapy for organisms that are moderately susceptible/intermediately susceptible can be variable. These organisms may respond to treatment with maximal doses of the antimicrobial or can respond when the drug is known to be concentrated at the site of infection, eg, urinary tract infections treated by drugs excreted by the kidneys. The S-DD designation was created to reduce ambiguity associated with the intermediate classification. Cefepime activity against Enterobacteriaceae is one such example. It carries the S-DD label against Enterobacteriaceae at MIC values of 4 to 8 mcg/mL. At these values, clinicians are advised to use higher-than-usual doses of up to 2 g every 8 hours. Along with cefepime, the CLSI has established S-DD breakpoints for daptomycin, ceftaroline, and fluconazole against specific pathogens, and the use of this designation is likely to expand in the future.[38]

There are concerns that the "user friendly" susceptible/resistant classification system can oversimplify the decision-making process for treating infections. For example, a critically ill patient may not respond to the antimicrobial therapy of a susceptible organism at the usual doses due to pharmacokinetic abnormalities, poor source control, or other host issues. Likewise, a patient with severe vascular insufficiency and a diabetic foot infection may fail a course of therapy with normal doses of an antimicrobial and a susceptible organism because of inadequate drug penetration. Additionally, variable outcomes can be achieved for "susceptible" organisms with elevated MIC values, and clinical and/or microbiologic cure rates can sometimes occur for infections that are caused by resistant organisms.[39] These reports emphasize that *in vitro* susceptibility does not correlate unequivocally with clinical success and that "resistant" organisms do not always equate with impending clinical failure.

Similarities in the spectrum of activity for classes of antibiotics have led to the concept of class testing. Thus, cephalothin susceptibility results are extrapolated to other first-generation cephalosporins, such as cephalexin or cefazolin. Likewise, susceptibility to an antibiotic that typically has reduced activity usually ensures that other more potent agents in its class will have reliable activity as well. However, many gram-negative organisms have now developed ESBLs that often have different activity against members of the same drug class. These developments significantly limit the utility of class testing to reduce susceptibility testing workload.

Deductive Susceptibility Testing by Detection of Resistance Factors

Chromogenic Detection of Resistance Determinants

There are several methods in use that directly detect the production of antimicrobial resistance in pathogens. β-Lactamase production can be detected rapidly and easily in the clinical laboratory with the use of nitrocefin disks. Nitrocefin is a chromogenic cephalosporin derivative that changes from yellow to red on hydrolysis by β-lactamase. Colonies from a growing bacterial culture can be touched to a disk, with β-lactamase production noted within a few minutes. Although rapid and reliable, this method is limited to the assessment of strains of staphylococci, enterococci, *H. influenzae*, *Moraxella catarrhalis*, and *N. gonorrhoeae*. The nitrocefin disk cannot detect β-lactam resistance caused by altered penicillin-binding proteins or by some of the newer ESBLs. The Rapidec® Carba-NP is a newer chromogenic system that detects carbapenemase-producing gram-negative organisms using principles similar to nitrocefin.

The detection of methicillin resistance in *Staphylococcus aureus* (MRSA) is crucial to ensure appropriate therapy. MRSA is commonly detected within 24 hours using chromogenic agar technology and a variety of such products are available, including chromID® MRSA and BrillianceTM MRSA 2, BBLTM CHROMagar®, MRSA II, and MRSASelectTM. This technology uses chromogenic substrates and a cephalosporin; MRSA strains will grow on an agar plate in the presence of cephalosporins such as cefoxitin and will produce differentially colored colonies resulting from hydrolysis of the chromogenic substrates. The sensitivity and specificity for these tests are often reported as >95% for the detection of mecA-positive strains.[40] chromID® MRSA and BrillianceTM MRSA 2 were significantly more sensitive than other chromogenic agars at detecting methicillin resistance mediated by the *mecC* gene, which is becoming more common in parts of Europe.[41] These tests can be preferable in small labs that don't have access to rapid molecular screening techniques but may be increasingly valuable in regions with increasing prevalence of mecC strains. A variety of chromogenic agars have been developed to detect gram-negative organisms that produce ESBLs or carbapenemases, rapidly identify *Listeria* in neonatal sepsis patients, and polymyxin resistance.[40] However, given the pace of development of new molecular tests it is unclear which of these agar-based methods will continue to be the most useful in the future and which will be replaced. Furthermore, a variety of chromogenic agars have been developed to detect gram-negative organisms that produce ESBLs or carbapenemases.[40]

Molecular Detection of Resistance Determinants

A variety of the molecular identification methods discussed earlier also include targets for drug resistance determinants. The detection of the *mecA* gene in staphylococci and the *vanA* gene in enterococci are some of the most commonly included targets on molecular probe and multiplex PCR panels. The *mecA* gene encodes the mutated penicillin-binding protein 2a (PBP2a) in *Staphylococcus* spp., which has low affinity for all traditional β-lactams. Due to the limitations of MIC testing discussed above, such as heterogeneous expression of resistance, molecular detection of the *mecA* gene is the most reliable and fastest way to identify MRSA or methicillin-resistant strains of coagulase-negative staphylococci. Similarly, the *vanA* gene, which encodes for a peptidoglycan variant with low affinity for glycopeptides and mediates high-level vancomycin resistance in enterococci, can be detected molecularly. Early detection of these resistance factor is crucial since most empiric regimens will not include an agent active against most strains of VRE.

Newer molecular panels such as the GeneXpert® Carba-R have targets for increasingly common carbapenemases including, KPC, NDM, VIM, IMP, and OXA-48. Similar to VRE, the rapid detection of carbapenemase-producing pathogens is critical since most patients will not receive empiric therapy that is active against these organisms.

ADVANCES IN SUSCEPTIBILITY TESTING FOR MYCOBACTERIA, FUNGI, AND VIRUSES

Advances have been made in the last decade in the areas of mycobacterial, fungal, and viral susceptibility testing. The use of radiometric techniques, such as the BACTEC TB460 system, was an important advancement in the analysis of antimicrobial susceptibility for *M. tuberculosis* and other slow-growing mycobacteria.[42] Use of this method, when coupled with the rapid processing of samples, reduced the time to susceptibility results to approximately 1 week. However, newer FDA-cleared mycobacterial susceptibility testing methods including the VersaTREK™ Myco Susceptibility Kit and the BACTEC Mycobacteria Growth Indicator Tube [MGIT 960] are fully automated and produce results in a similar time frame and with similar reliability as the radiometric method but without radioactive compounds.[43] Although the slower agar proportion susceptibility method (generating results in approximately 1 month) is still considered the reference standard for mycobacterial susceptibility testing by the CLSI, the group now recommends the use of a rapid susceptibility testing method to ensure that the Centers for Disease Control and Prevention (CDC) guidelines for reporting susceptibility results for *M. tuberculosis* infections within 28 days of specimen receipt in the laboratory can be met. The use of molecular probes such as the Xpert® for mycobacterial resistance genes has become a more important component of mycobacterial susceptibility determinations, especially considering the increasing problems with antimicrobial resistance.[44]

PCR has now become a standard method to quantify the replication of HIV and hepatitis viruses in infected patients (the viral load described expressed as copies per milliliter). Similar methods are used to determine the presence of genetic mutations in the HIV that are associated with increased resistance to one or more of the many antiretroviral medications available for clinical use. The use of these genotyping methods as an aid to select an optimized antiretroviral regimen has been correlated with an improved clinical response to therapy, as well as with a more potent reduction in the viral load.[45]

SPECIAL *IN VITRO* TESTS OF ANTIMICROBIAL ACTIVITY

⑧ Some pharmacodynamic tests are not routinely performed in the clinical microbiology laboratory but are nevertheless useful for the clinician to understand conceptually when making therapeutic decisions. These tests are performed in research labs and are often reported in the literature.

Minimum Bactericidal Concentration

⑦ The minimum bactericidal concentration (MBC) can be performed in conjunction with the broth microtiter MIC test by taking aliquots of broth from microtiter wells that demonstrate no visible growth and plating the samples onto antibiotic-free agar plates for subsequent incubation. The MBC is defined as the lowest concentration of drug that kills 99.9% of the total initially viable cells (representing a 3 $\log_{10}$ CFU/mL [6 $\log_{10}$ CFU/L] or greater reduction in the starting inoculum). For certain antibiotic classes such as the aminoglycosides and the quinolones, the MIC often approximates the MBC. However, for β-lactam antibiotics and glycopeptides, the MBC can exceed the MIC substantially, resulting in an overestimation of *in vivo* bactericidal activity. When the MBC exceeds the MIC by 32-fold or more, an organism is sometimes said to be tolerant to the antimicrobial's killing activity. Although the phenomenon of tolerance has been documented for a variety of drugs and pathogens, there is limited evidence to suggest that it correlates well with clinical failure. Recent systematic reviews of the literature have failed to a differentiate in outcomes of patients treated with bactericidal versus bacteriostatic drugs.[46]

Time-Kill Curve Tests

Time-kill curve tests are not performed routinely in the clinical laboratory but can provide important additional data on the effects of an antimicrobial on bacteria. For time-kill curve tests, a standard inoculum of bacteria (10^6 CFU/mL [10^9 CFU/L]) is suspended in a test tube containing liquid growth medium with or without desired test concentrations of antimicrobial(s). Samples are removed periodically, usually over a 24-hour period, to determine the number of living cells at the given time points. The viable cell counts are plotted versus time to construct the time-kill profile of the antimicrobial. The tested concentration of antimicrobial is considered to be bactericidal if it causes at least a 3 $\log_{10}$ CFU/mL (6 $\log_{10}$ CFU/L) reduction in viable inoculum. Comparisons of the relative rates of bacterial killing of different drugs, exposures, or combinations can also be performed in time-kill curve experiments. Additionally, optimal PK/PD indices can be determined from a time-kill curve experiments. An example of results from a time-kill curve experiment is depicted in **Fig. e122-7**. These data can help predict the best way to administer an antimicrobial to maximize activity. For example, lower-dose, more frequent (or even continuous) infusions would be preferable for concentration-independent antibiotics (ie, time dependent), while higher doses administered intermittently would maximize activity for concentration-dependent antibiotics.

FIGURE e126-7

Killing curve depicting the effect of concentration on antibiotic bactericidal activity. (CFU, colony-forming unit; MIC, minimum inhibitory concentration [0.25-64 times the MIC; the organism tested was *P. aeruginosa* ATCC 27853]). *(Data from Craig WA, Ebert SC. Killing and regrowth of bacteria in vitro: A review. Scand J Infect Dis Suppl 1991;74:63-70.)*

Postantibiotic Effect

The postantibiotic effect (PAE) is defined as the persistent suppression of an organism's growth despite antibiotic concentrations falling below the MIC.[47] A PAE experiment is performed by exposing a fixed inoculum of organism to a set concentration of antibiotic (typically some multiple of the MIC) (**Fig. e122-8**). The antibiotic is then removed by inactivation (eg, inactivation by a β-lactamase or binding the antibiotic to a resin), dilution, or filtration/centrifugation of the mixture. The cells are resuspended in antibiotic-free growth medium, and samples are removed frequently (every 0.5-2 hours) to determine resumption of normal growth. The PAE is quantified as the difference in time that it takes the organism exposed to the antibiotic to demonstrate a 10-fold increase in viable cells per milliliter as compared with a separate culture of organism not subjected to the antibiotic. A PAE equal to or greater than 1 hour has been demonstrated for most antibiotics against gram-positive bacteria, including β-lactams, vancomycin, daptomycin, linezolid, and telavancin. Generally, antibiotics that inhibit DNA or protein synthesis (eg, quinolones and aminoglycosides) demonstrate significant PAEs against gram-negative organisms. An exception to this rule is the carbapenems (eg, doripenem, imipenem, and meropenem), which inhibit cell wall synthesis, but demonstrate PAEs against selected strains of gram-negative organisms such as *P. aeruginosa*. The primary clinical application of the PAE is to allow for less frequent administration of antimicrobials while still maintaining adequate antibacterial activity (eg, extended-interval aminoglycoside administration).[47]

FIGURE e126-8

Postantibiotic effect (PAE). In this experiment, fixed inocula of *Staphylococcus aureus* and *Pseudomonas aeruginosa* are exposed to ticarcillin, imipenem, and ciprofloxacin at a set concentration of four times the MIC. The organism and the antibiotic are then diluted 1,000-fold to a point where the antibiotic concentration is far below the MIC of the organism. Growth suppression of *S. aureus* following exposure to the three drugs (PAE) occurs for approximately 2 hours. Growth suppression of *P. aeruginosa*, however, is only demonstrated for imipenem and ciprofloxacin. The β-lactam ticarcillin has no effect on the growth of *P. aeruginosa*. (CFU, colony-forming unit; MIC, minimum inhibitory concentration.) *(Data from Craig WA, Ebert SC. Killing and regrowth of bacteria in vitro: A review. Scand J Infect Dis Suppl 1991;74:63-70.)*

Antimicrobial Combination Effect Test

Antimicrobial combination therapy is used frequently for empiric therapy and to treat serious infections due to multidrug-resistant organisms. Combination therapy can be used prior to knowing the pathogen or antibiotic susceptibility for the treatment of infections in neutropenic patients and as definitive therapy for specific infections such as enterococcal endocarditis or bacteremia, sepsis, or pneumonia caused by *P. aeruginosa,* among other situations. In these cases, it is important to know whether the combination will have beneficial or detrimental effects on the overall antimicrobial activity of the regimen. For example, the combination can result in activity that is far greater than the activity of either agent alone, known as synergy. Conversely, the combination can result in activity that is worse than the most active agent alone, referred to as antagonism. Combination activity that is neither synergistic nor antagonistic is said to be indifferent or sometimes additive.[48]

There are two main research methods used to determine the expected effects of combination antibiotic therapy. The first method is the microtiter fractional inhibitory concentration (FIC, or "checkerboard" method), in which antibiotics are tested in combination in microwell trays, and the MIC of the antibiotic in combination is compared to the MIC of that agent alone. Criteria for synergy, indifference, and antagonism have been established for FIC indices.[49] This method has fallen out of favor in the last several decades due to increased specificity of the time-kill assays. The time-kill assays determine the effects of antibiotic combinations by combining two antibiotics to the same test tube at fixed concentration fractions of the MIC for each drug, and killing is quantified at multiple time points over, usually, 24 hours. With this method, synergy is defined as a 100-fold decrease in viable organisms at 24 hours for the combination as compared with the most potent antibiotic tested alone. Antagonism is defined as a 10-fold or greater increase in viable organism count (**Fig. e126-9**).[48] Although antagonism has been demonstrated for several combinations *in vitro* (eg, penicillin plus tetracycline, chloramphenicol plus aminoglycoside, fluoroquinolones and rifampin), theoretically antagonistic combinations do not always result in worse outcomes *in vivo*.

FIGURE e126-9

Time-kill curve illustrating indifference, synergy, and antagonism. (CFU, colony-forming unit.)

Although the methods for testing the effects of antimicrobial combinations are well described, the results from these tests have not been adequately studied in the context of many infection outcomes. There is little debate that the combination therapy, typically consisting of a β-lactam antibiotic and an aminoglycoside, is required for successful treatment of enterococcal endocarditis. For enterococci, susceptibility to high concentrations of aminoglycosides (eg, gentamicin, 500 mg/mL [g/L]) is evaluated in the clinical laboratory because it correlates closely with synergy when the drug is combined with β-lactam antibiotics. *In vitro* synergy data with two β-lactams, namely ampicillin and ceftriaxone, has led to clinical studies which have shown this regimen to be similarly efficacious and less toxic than the aminoglycoside-based combinations.[50]

The concept of combination therapy is not universally accepted for the treatment of other infections. There is ongoing debate as to whether the combination of a broad-spectrum β-lactam with an aminoglycoside is needed (vs the β-lactam alone) for invasive gram-negative infections or infections in neutropenic patients. In individual studies, combination therapy has resulted in improved outcomes in patients with severe illness and in patients with *P. aeruginosa* bloodstream infections, but pooled meta-analyses have disputed these results and discourage the use of aminoglycosides in combination with β-lactams in septic patients due to increased rates of nephrotoxicity.[51]

LABORATORY MONITORING OF ANTIMICROBIAL THERAPY

⑨ Monitoring serum concentrations is the most common method for maximizing efficacy and minimizing toxicity of antimicrobials. Because most antimicrobials are well tolerated at their usual doses, few agents, eg, aminoglycosides, vancomycin, and select antifungals, are monitored routinely in the current clinical environment. However, emerging data suggesting the benefit of monitoring a wider variety of agents has led some centers to begin broader therapeutic drug monitoring programs. The most common analytical methods for measuring antimicrobial concentrations in the clinical lab include fluorescence-polarization immunoassay (FPIA), enzyme immunoassay (EMIT), and enzyme-linked immunosorbent assay (ELISA), but other assays such as radioimmunoassay and high-performance liquid chromatography (HPLC) have been used as well.

TIMING OF COLLECTION OF SERUM SAMPLES

⑨ Peak and/or trough concentrations are monitored routinely for only a select few antimicrobials (eg, aminoglycosides and vancomycin) during the contemporary management of infections. It is crucial for the healthcare team to ensure that antimicrobial administration time and serum sample time(s) are meticulously recorded because even small errors in recording these values (eg, 1 hour) can have a substantial impact on the calculation of the pharmacokinetics for antibiotics such as the aminoglycosides, which have relatively short elimination half-lives.

⑩ Samples ideally should be obtained after steady state is achieved (usually defined as the passage of at least four to five anticipated half-lives), but in certain situations, this may not be possible, eg, critically ill patients with fluctuations in drug elimination owing to fluctuating hemodynamics, kidney function, and/or liver function. Generally, the timing of the peak serum sample collection is usually more critical than the trough concentration because adequate time must elapse to allow for completion of the distribution phase and to avoid underestimating the drug’s volume of distribution.

MONITORING OF SPECIFIC AGENTS

Aminoglycosides

⑪ The aminoglycosides and vancomycin remain the most common agents for which serum concentrations are monitored. There are many studies that have linked serum aminoglycoside concentrations with clinical response and with the occurrence of nephrotoxicity. One of the classic investigations into the relationship between serum aminoglycoside activity and clinical outcome revealed that peak serum concentrations of at least 5 mcg/mL (mg/L; ~11 μmol/L) for gentamicin and tobramycin and at least 20 mcg/mL (mg/L; 34 μmol/L) for amikacin were associated with a lower prevalence of clinical failure rates during the treatment of gram-negative bacteremia.[52,53] Although earlier studies suggested that trough concentrations exceeding 2 to 4 mcg/mL (mg/L; ~4-8 μmol/L) for gentamicin and tobramycin and 10 mcg/mL (mg/L; 17 μmol/L) for amikacin predisposed patients to nephrotoxicity, other investigations indicated that the development of aminoglycoside-related ototoxicity and nephrotoxicity is more complex and also is associated with the total exposure to the aminoglycoside (as measured by the area under the curve [AUC]) and/or the total duration of aminoglycoside therapy).[52,54] The specific recommended serum peak and trough concentrations for various aminoglycosides are described in **Table e126-2**.

TABLE e126-2

Suggested Therapeutic Serum Concentrations for Selected Antimicrobial Agents

Drug	Sample	Target Concentrations (mg/L [µmol/L])	Comments
Gentamicin, tobramycin (traditional dosage regimens)	Peak (1 hour after start of 15- to 45-minute infusion)	<5 (11 µmol/L)	Urinary tract infections
		>5 (11 µmol/L)	Bacteremia
		>6 (13 µmol/L)	Bacterial pneumonia
		>12 (25 µmol/L)	Endocarditis caused by *Pseudomonas aeruginosa*
	Trough	<2-3 (4-6 µmol/L)	High trough concentrations are most likely a result of and not a cause of nephrotoxicity.
Amikacin	Peak	>15 (26 µmol/L)	Urinary tract infections
		>20 (34 µmol/L)	Bacteremia
		>24 (41 µmol/L)	Bacterial pneumonia, other serious infections
	Trough	>9-10 (15-17 µmol/L)	See comments regarding trough gentamicin/tobramycin concentrations
Single daily dosage regimens			
Gentamicin	8-hour postdose (*mid-dose*)	1.5-6 (3-13 µmol/L)	Concentrations above this range associated with nephrotoxicity in one study with netilmicin
Netilmicin			
Tobramycin			
Vancomycin (for serious MRSA infections		15-20 (10-14 µmol/L) 400-600 mg × hr/L (276-414 µmol × hr/L)	New guidelines recommend AUC-guided dosing rather than troughs (see text)

Data from References 55 and 56.

Newer regimens of high dose once-daily or extended-interval aminoglycoside administration have gained widespread acceptance for use in the clinical setting. These regimens exploit the pharmacodynamic properties of these agents (ie, concentration-dependent bacterial killing and a substantial PAE) to maximize activity while also attempting to minimize drug nephrotoxicity by reducing the total aminoglycoside exposure time for the patient's kidneys. The doses employed for extended-interval treatment typically range from 5 to 7 mg/kg of total, ideal, or adjusted body weight administered every 24 hours, with the dose and/or interval adjusted based on renal function or observed mid-dose serum concentrations.[57] Many prospective studies have been performed to evaluate the safety and efficacy of once-daily aminoglycoside dosing, and most have revealed similar rates of efficacy and toxicity, or trends toward improved efficacy and reduced toxicity for once-daily dosage regimens as compared with traditional (thrice daily) regimens.

Traditional methods of aminoglycoside serum concentration monitoring (evaluating peak and trough serum concentrations) cannot be applied to extended-interval dosing because the serum concentrations 24 hours after a dose ideally should be undetectable. A mid-interval serum sample can be taken approximately 6 to 12 hours after the dose to allow for use of first-order pharmacokinetic equations or nomograms for interval adjustments.[57]

Vancomycin

⑫ Although IV vancomycin has been associated with oto- and nephrotoxicity in humans, most of these reports occur when vancomycin is combined with known nephrotoxic agents. Although serum peak and trough concentrations were previously recommended for monitoring vancomycin therapy, only trough concentrations have been monitored because of concentration-independent killing of bacteria by vancomycin. Specifically, vancomycin trough concentrations of 15 to 20 mg/L (10-14 µmol/L) have been recommended for more serious infections such as bloodstream infections, pneumonia, endocarditis, and meningitis caused by *S. aureus* because of a number of factors including (a) poor penetration into tissue such as the lung, (b) the association of the emergence of vancomycin-nonsusceptible strains in patients who had trough serum concentrations maintained below 10 mg/L (7 µmol/L), and (c) the trend of higher vancomycin MICs for most strains of staphylococci. However, the American Society of Health-System Pharmacists (ASHP), the Infectious Diseases Society of America (IDSA), and the Society of Infectious Diseases Pharmacists (SIDP) have recommended that vancomycin dosing be adjusted based on the area-under-the-concentration-time-curve to MIC ratio (AUC/MIC) for infections caused by MRSA. The AUC/MIC is the parameter that best predicts efficacy as demonstrated by both animal and human data.[55] Achieving a free-fraction (unbound) area-under-the-curve to MIC ratio (*f*AUC/MIC) of greater than or equal to 211 or a total AUC/MIC of greater than 400 improved outcomes of patients with *S. aureus* bacteremia and/or endocarditis. With trough concentrations of 15 to 20 mg/L (10-14 µmol/L) used as a surrogate marker for success, the assumption was that a therapeutic AUC/MIC was achieved.[56] However, newer data have demonstrated that the traditional trough-only approached underestimates up to 34% of vancomycin treated patients.[58,59] Additionally, nephrotoxicity rates are substantially lower when utilizing AUC versus trough dosing and monitoring.[49] The current version of the vancomycin dosing guidelines suggest an AUC/MIC target of 400 to 600 to be achieved within the first 24 to 48 hours of infection due to MRSA.[58] These monitoring recommendations for vancomycin extend to infections due to MRSA only. Infections due to other organisms do not have the data to support therapeutic drug monitoring of vancomycin.

While the process of calculating AUC for each vancomycin dosing regimen may appear daunting, AUC can be calculated in multiple ways, and the guidelines recommend either of the following methodologies to determine AUC in clinical practice. In patients with two vancomycin serum concentrations, AUC can be calculated by dividing the dose received by the patient-specific clearance. Correct timing and documentation of blood draws and pharmacokinetic calculations are required for this strategy, which may require additional training and coordination of medical staff. For patients with only one concentration, an AUC can be estimated by maximum a posteriori (MAP) probability Bayesian software. While this methodology requires little calculation from a clinician, specialized software and clinician training is required to successfully employ this method of AUC monitoring. Precise timing of the vancomycin dose and concentration is needed for these estimations.

USING PHARMACODYNAMICS TO IMPROVE ANTIMICROBIAL THERAPY

⑬ ⑭ Antimicrobial regimens should be selected and/or designed to maximize the probability that bacterial killing is optimized and that the probability of resistance is minimized. For example, the activity of the aminoglycosides can be maximized if the ratio of the peak serum concentration to the organism MIC (peak-to-MIC ratio) is greater than or equal to 10.[60] Similarly, the probability of clinical and/or microbiologic cure can be maximized if a fluoroquinolone is chosen that achieves an AUC-to-MIC ratio of 100 to 125 or greater for gram-negative bacteria (eg, *P. aeruginosa*) and 30 to 40 or greater for gram-positive bacteria (eg, *S. pneumoniae*) (Fig. e126-10).[60]

FIGURE e126-10

Illustration of the concept of peak concentration to the MIC ratio for aminoglycosides. The MIC for the given organism to gentamicin is 2 mg/L, whereas the tobramycin MIC is 0.5 mg/L. Administration of gentamicin would result in a suboptimal peak: MIC ratio (<10), which could increase the chances for development of resistance or an inadequate response. Administration of tobramycin would result in a peak: MIC ratio of 12, which should improve efficacy. Note that modification of the gentamicin regimen to produce peak serum concentrations of 20 mg/L (42 µmol/L) or more (as commonly done with once-daily administration) also would result in a peak: MIC ratio of ≥10.

To date, most of the data on optimization of antimicrobial pharmacodynamics have been generated in *in vitro* models of infection, in animal models of infection, or through mathematical modeling of small data sets. However, research continues to emerge on the best ways to apply these valuable data to the everyday management of patients in the clinical setting. The recognition of the importance of antimicrobial pharmacodynamics has already resulted in therapeutic innovations such as (a) the expansion of serum concentration monitoring for select antimicrobials (eg, antiretroviral agents, antifungal agents), (b) revisions of breakpoint values that define antimicrobial susceptibility and/or resistance, (c) development of nomograms or computer programs that can suggest optimal drugs and doses for given infections, (d) novel administration methods such as prolonged infusion times for antibiotics such as β-lactams with time-dependent activity, and (e) the development of newer antimicrobial agents with minimized risks of suboptimal pharmacodynamics. These developments present exciting opportunities for healthcare providers to improve the outcomes of patients with infections in a variety of different healthcare settings.

SELF-ASSESSMENT QUESTIONS

1. Choose the correct statement(s) regarding the WBC count and differential.

A. WBC count is usually elevated in response to infection.

B. The normal range of the WBC count is 12,500 to 20,000 cells/mm^3 (12.5 × 10^9 - 20.0 × 10^9/L).

C. WBC count is nonspecific and can be elevated in response to a number of noninfectious conditions.

D. Neutrophils are the most common type of WBC in the blood.

E. A, C, and D are correct statements.

2. The inflammatory process initiated by infection can set up a complex set of host responses which include:

A. Activation of the complement cascade

B. An increase in the erythrocyte sedimentation rate

C. Elevations of C-reactive protein

D. Increased production of interleukins and tumor necrosis factor

E. All of the above

3. Which of the following circumstances would be considered the most consistent with colonization by normal microbiota?

A. *S. epidermidis* found on the skin

B. *S. aureus* in the bloodstream

C. *E. coli* in the urine

D. *Viridans* streptococci found in the nasopharynx

E. Both A and D

4. Choose the correct statement(s) regarding the identification of potential pathogens

A. The Gram stain may provide a presumptive diagnosis and identify whether the pathogen is gram-positive or gram-negative and a bacillus or coccus.

B. Cultures can provide definitive pathogen identification and differentiate organisms on the basis of biochemical characteristics more rapidly than molecular-based methods.

C. MALDI-TOF MS can rapidly speciate most microbes on the basis of genetic markers.

D. Even with automated systems, detection of bacteria or fungi within a few hours is not yet possible.

E. All of the above.

5. Although widely employed, the use of molecular methods is often limited by these tests’ lack of sensitivity.

A. True

B. False

6. Which of the following is an appropriate description of an element of nucleic acid amplification?

A. Polymerase chain reaction (PCR) is based on the capability of a DNA polymerase to copy and elongate a targeted segment of DNA.

B. Each PCR cycle theoretically doubles the amount of DNA originally present in a sample.

C. PCR techniques are useful for detecting fastidious or slowing growing organisms.

D. Genetic markers for resistance for *M. tuberculosis* and methicillin-resistant *S. aureus* are two examples where PCR techniques have been employed.

E. All of the above.

7. Which of the following technologies is NOT currently used for rapid identification of potential pathogens?

A. Mass spectrometry.

B. Multiplex PCR

C. Enzyme-linked immunosorbent assays.

D. All of the above are used for rapid identification of potential pathogens.

8. Which of the following statements is most accurate regarding microtiter MIC testing?

A. Microtiter MICs are difficult to perform via automated procedures.

B. Microtiter MICs have little to no value in the contemporary management of infections.

C. Microtiter MICs may overestimate or underestimate *in vivo* antimicrobial activity.

D. Microtiter MICs are capable of reporting any number of potential minimum inhibitor concentrations and are not limited to doubling dilutions.

9. Which of the following statements describing susceptibility testing is most correct regarding susceptibility testing?

A. MIC is defined as the lowest concentration of a given antimicrobial that will kill 99.9% of the patient's organism after 16 to 24 hours of incubation.

B. MIC is defined as the lowest concentration of given antimicrobial that will inhibit visible growth of an organism after 16 to 24 hours of incubation.

C. Kirby–Bauer test is a quantitative susceptibility test that can provide an MIC value.

D. An Etest is a qualitative test used to measure susceptibility and resistance for an antibiotic against a given pathogen.

10. MM is a patient with pneumonia, a lung abscess, and stage 3 chronic kidney disease. Methicillin-resistant *Staphylococcus aureus* (MRSA; susceptible to vancomycin via microtiter MIC) grew from a bronchoalveolar lavage sample. Vancomycin therapy was started, but the patient has not responded to 7 days of therapy. Which of the following would be the MOST likely explanation for the failure?

A. The presence of vancomycin-resistant *Staphylococcus aureus* (VRSA).

B. The patient's reduced kidney function due to stage 3 chronic kidney disease is increasing vancomycin clearance.

C. Inadequate penetration of the vancomycin to the site of the infection in the lung.

D. Suboptimal peak to MIC ratio.

11. Which of the following statements is FALSE concerning antimicrobial susceptibility testing and its application to the management of infections?

A. An infection due to an antimicrobial-resistant organism is unlikely to respond to treatment with even maximal doses of that antimicrobial.

B. The Kirby–Bauer disc diffusion test results in quantifiable MIC data that allows dose optimization of antibiotic therapy.

C. Automated susceptibility test systems can interface with pharmacy records to help assess appropriateness of antimicrobial therapy.

D. Newly developed testing methods for mycobacteria have reduced susceptibility reporting time to less than 28 days

12. A patient has a lung infection due to *Pseudomonas aeruginosa*. He is currently receiving therapy with a fluoroquinolone that on average produces a peak serum concentration of 5 mcg/mL (mg/L) and an AUC of 100 mg x h/L. The MIC for this fluoroquinolone against his infecting pathogen is 2 mcg/mL (mg/L). Which of the following statements is TRUE.

A. The data provided are incomplete, since fluoroquinolones demonstrate time-dependent pharmacodynamics and we need the trough value to determine the time above the MIC.

B. The fluoroquinolones demonstrate concentration-dependent pharmacodynamics and the peak-to-MIC ratio is optimized for this pathogen at the current dose.

C. The fluoroquinolones demonstrate exposure-dependent pharmacodynamics and the AUC-to-MIC ratio is optimized for this pathogen at the current dose.

D. The fluoroquinolone should be avoided in this instance due to suboptimal pharmacodynamics and a low probability of clinical cure.

13. Which of the following statements is FALSE concerning “once-daily” (extended interval) aminoglycoside dosage regimens?

A. The higher doses produce higher peak serum concentrations than conventional doses, which maximize antimicrobial activity.

B. Peak and/or mid-dose serum concentrations should be routinely monitored.

C. Nomograms can be used to determine dosage regimens.

D. Limitations in the clinical studies of “once daily” regimens have prevented widespread use.

14. Which of the following statements is FALSE concerning special *in vitro* tests of antimicrobial susceptibility?

A. Demonstration of *in vitro* antagonism for two antimicrobials does not always correlate with poor clinical outcomes when those antimicrobials are used together in patients.

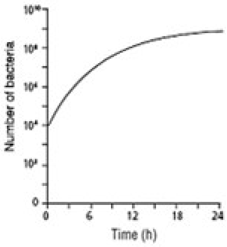
B. MBCs can be helpful to guide antimicrobial treatment of infections such as infective endocarditis or osteomyelitis.

C. Time-kill curve tests can be used to measure the effect of antimicrobial concentration on bacterial survival.

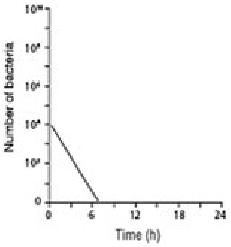
D. The administration interval can be prolonged for an antimicrobial with a postantibiotic effect.

15. Which figure(s) is/are the most appropriate representation of how bacteria are affected by the presence of an antibiotic to which they are fully susceptible?

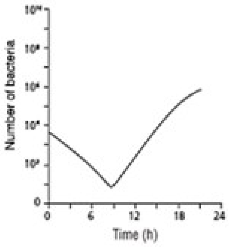
A



B



C



A. Figure A only

B. Figure B only

C. Figure C only

D. Figures A and C

Chapter e132: Coronavirus disease (COVID-19)

Jason M. Pogue; Erin K. McCreary; Julie Ann Justo

CHAPTER SUMMARY

All information in this chapter is current as of July 20, 2021. The COVID-19 pandemic is a rapidly evolving situation with frequently changing information. While this text should serve as a foundational reference, the National Institutes of Health (NIH) and Infectious Diseases Society of America (IDSA) COVID-19 Treatment Guidelines and the Centers for Disease Control and Prevention (CDC) COVID-19 Vaccination site should be referenced electronically for the most current treatment and prevention recommendations.

KEY CONCEPTS

KEY CONCEPTS

1. Coronavirus disease 2019 (COVID-19), caused by the SARS-CoV-2 virus, is associated with high morbidity and mortality particularly among patients 65 years of age and older, those with chronic comorbidities, and/or patients of select racial and ethnic backgrounds.
2. The primary route of transmission of SARS-CoV-2 is direct person-to-person respiratory transmission via infected particles (i.e., droplets, aerosols). Risk of transmission is greatest for individuals in close contact for a significant period of time, especially while indoors. Transmission can occur from symptomatic, presymptomatic, or asymptomatic individuals.
3. COVID-19 disease progression occurs in three phases of increasing severity: (i) early infection, (ii) pulmonary phase, and (iii) hyperinflammation. The majority of patients recover in the early infection phase; yet a small proportion may progress to the pulmonary (14%) and hyperinflammation (2-5%) phases.
4. Signs and symptoms typically emerge 4 to 5 days from onset of infection but may occur sooner or take up to 14 days to manifest. Common symptoms include fever, cough, shortness of breath, loss of taste or smell, and fatigue. Oxygen saturation and patient location (hospitalized vs. non-hospitalized) are defining characteristics that determine eligibility for specific pharmacotherapy.
5. Symptomatic COVID-19 is diagnosed by a positive nucleic acid amplification test (NAAT) for SARS-CoV-2 or an antigen test. Asymptomatic infection is a positive test in the absence of symptoms. Probable COVID-19 can be diagnosed by a compatible syndrome in either the absence of viral testing or a negative test. False negative tests are most common early in infection.
6. Three vaccines are available in the United States under Emergency Use Authorization (EUA): two as a two-dose series using an mRNA technology platform (Pfizer, Moderna) and one as a one-dose injection using an adenovirus vector platform (Johnson & Johnson).
7. All patients eligible should receive a vaccine as soon as possible to prevent COVID-19. There is no preferential recommendation between vaccines and choice should be primarily based on vaccine availability. Patient-specific preferences, including, but not limited to, the desire for a one versus two dose option and individual risk factors for rare adverse events, should be taken into consideration.
8. Monoclonal antibodies (bamlanivimab and etesevimab, casirivimab and imdevimab, or sotrovimab) can decrease the need for hospitalization in outpatients with mild-moderate COVID-19 if administered within 7 days of symptom onset.
9. Remdesivir is the only antiviral agent approved by the US Food and Drug Administration for treatment of COVID-19. It may shorten time to clinical recovery by up to 2 days in patients receiving supplemental oxygen.
10. Dexamethasone is a corticosteroid that decreases all-cause mortality in patients with severe COVID-19 requiring supplemental oxygen. Other immunomodulatory therapies, such as the IL-6 antagonist tocilizumab, or the Janus kinase inhibitor baricitinib, can further decrease mortality when used in combination with corticosteroids in patients with severe COVID-19 and elevated inflammatory markers who are requiring supplemental oxygen.

PATIENT CARE PROCESS

PATIENT CARE PROCESS

Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics: age, sex, race, ethnicity, social living arrangements, travel history, current health status (e.g., chief complaint), past and present medical history, allergies
- Medication history: Non-prescription medications, herbal products, dietary supplements, prescription medications (including prior antiviral or other antimicrobial use), vaccination history
- Subjective data
    - Signs and symptoms including fever, cough, shortness of breath, diarrhea, new loss of taste or smell
- Objective data
    - Vitals: Blood pressure (BP), heart rate (HR), respiratory rate (RR), temperature, O_2 saturation, need for supplemental oxygen, height, weight
    - Labs: Complete metabolic panel including serum creatinine (SCr), liver function tests; complete blood count with differential; markers of inflammation (C-reactive protein, D-dimer, ferritin)
    - Microbiologic & Molecular Testing Data: Molecular, antigenic, and/or serologic viral testing; Other microbiologic testing for bacterial or fungal infections (if available)
    - Radiographic Imaging, e.g., chest X-ray, computed tomography (CT) of the chest

Assess

- Assess any recent exposure to an individual with COVID-19 or other high-risk activities for exposure to SARS-CoV-2
- Assess COVID-19 vaccination status
- Determine severity of illness (e.g., radiographic evidence of pulmonary infiltrates, O_2 saturation, hemodynamic stability)
- Determine comorbidities or other risk factors for disease progression (e.g., age, sex, comorbidities, immunocompromised status, race, and ethnicity)
- Assess baseline liver function for safety of drug therapy and progression of disease
- Estimate creatinine clearance for safety of drug therapy and dosing
- Assess for medication contraindications and/or drug interactions
- Assess patient eligibility for clinical trials as applicable based on local availability and opportunity for trial enrollment
- Determine likelihood of co-infection of the respiratory tract

Plan*

- Assess eligibility for monoclonal antibody therapy based on Emergency Use Authorization (EUA) criteria and facilitate administration (typically in the outpatient setting)
- Initiate antiviral therapy based on severity of illness, if appropriate
- Initiate immunotherapy (e.g., corticosteroids) based on severity of illness, as appropriate
- Determine goals of therapy, monitoring parameters to determine efficacy and safety of each therapy, and frequency and timing of follow-up
- Determine appropriate antibiotic or antifungal therapy for secondary bacterial or fungal infection, with an associated monitoring plan
- Determine appropriate management strategy for drug interactions and/or drug dosing based on end-organ function
- Patient education (e.g., infection prevention practices, purpose of treatment, drug-specific information, medication administration, adverse event counseling, informed consent for

clinical trials)

- Recommend vaccinations as indicated for prevention once patient has recovered from acute illness

Implement[*]

- Initiate disease-appropriate pharmacotherapy
- If bacterial or fungal co-infection suspected, initiate empiric antibiotic or antifungal therapy and de-escalate to narrower-spectrum antimicrobials or discontinue as appropriate based on clinical response and microbiologic data
- Ensure all necessary monitoring parameters are determined
- Provide patient education regarding all elements of treatment plan
- Enroll in clinical trials, if applicable
- Coordinate care to provide recommended vaccinations once patient has recovered from acute illness

Follow-up: Monitor and Evaluate

- Resolution of signs and symptoms (e.g., hypoxia, shortness of breath, cough, fever)
- Presence of adverse effects (e.g., transaminitis, gastrointestinal disturbance, secondary infections, hyperglycemia)
- Regulatory reporting (e.g., clinical trials, MedWatch, VAERS)
- Evaluate availability of resources and patient readiness to prevent further transmission

[*] Collaborate with patient, caregivers, and other health professionals

BEYOND THE BOOK

- Two 15-minute podcasts with all 3 authors focusing on:
    - Brief clinical approach to managing COVID-19 (e.g., prevention, stratifying disease severity, determining locally available experimental therapies)
    - Providing clinical pearls for pandemic preparedness and staying up to date with rapidly changing clinical evidence/guideline recommendations

INTRODUCTION

Coronavirus disease 2019 (COVID-19) is a widespread, life-threatening infection caused by SARS-CoV-2. An epidemiological alert was placed with the World Health Organization (WHO) on December 31st, 2019 after several patients in Wuhan, China were diagnosed with an unexplained pneumonia.[1] The WHO declared a pandemic on March 11, 2020.[2] In the first year of existence, SARS-CoV-2 infected over 83 million people worldwide resulting in 1.82 million deaths.[3]Remarkably, scientists developed multiple effective vaccines to prevent SARS-CoV-2 infection within a year of virus isolation and sequencing.[4-7] COVID-19 vaccination is one of the most important global public health measures to stop the exponential spread of infection and to prevent significant morbidity and mortality. Hundreds of pharmacological agents have been evaluated for COVID-19 prevention and/or treatment with limited success. Therapies with proven efficacy are limited to passive immunity via monoclonal antibodies, one antiviral agent, and multiple agents targeting the inflammatory cascade in severe illness. The approach to clinical management of COVID-19 is based on staging the severity of illness.

ETIOLOGY AND EPIDEMIOLOGY

SARS-CoV-2 is a single-stranded positive-sense RNA virus belonging to the family *Coronaviridae* and the genus *Betacoronavirus*.[8] The term “coronavirus” stems from the Latin root *corona*-, meaning “crown” or “halo,”—so named after the characteristic spike proteins which surround the surface of the virus. Other disease outbreaks caused by betacoronaviruses include Severe Acute Respiratory Syndrome (SARS-CoV-1) and Middle Eastern Respiratory Syndrome (MERS-CoV).

The original source of SARS-CoV-2 infection in humans remains unknown; however, many early cases were associated with exposure to an animal market in Wuhan, China.[9] Theorized origins under investigation include either direct transmission from an infected animal to humans (e.g. bat to human), indirect transmission through an intermediate host (e.g. bat to pangolin to human), or introduction to humans through cold or food chain products or a laboratory incident. The closest known viral sequence is that of the RaTG13 virus found in a horseshoe bat, which shares 96.2% homology with SARS-CoV-2.[8]

Data from the Centers for Disease Control and Prevention (CDC) estimate the cumulative incidence of COVID-19 in the United States (US) from February 2020 to March 2021 was 114.6 million total infections, 97.1 million symptomatic infections, and 5.6 million hospitalizations.[10] The estimated COVID-19 infection rate was 35,047 cases per 100,000, suggesting COVID-19 may have infected over a third of the US population in this period. Of note, these data are adjusted for estimated rates of underreporting. Individuals aged 18 to 49 years were estimated to comprise the highest proportion of both total (49%) and symptomatic COVID-19 infections (49%); however, elderly individuals aged 65 years or older were estimated to comprise the highest percentage of hospitalized patients (47%).

COVID-19 quickly spread from China to countries throughout the world including those in Europe, the Middle East, and the Americas. Within the US, COVID-19 incidence rates to date have been characterized by three distinct surges. The first surge in March and April 2020 represented the initial rapid spread of the virus to "hot spots," such as the state of New York. The second surge in July and August of 2020 was characterized by more widespread transmission, especially across southern states such as Florida, Arizona, Texas, and California. The third and largest surge was in November 2020 through January 2021 and was widespread throughout the country. Periodic surges in COVID-19 cases continue to occur, especially in countries around the world or regions within the US with low COVID-19 vaccination rates.

As COVID-19 continues to spread, the virus is evolving in its human host. This has led to the emergence of SARS-CoV-2 variants with one or more genetic mutations that may result in increased transmissibility; increased virulence; and/or decreased effectiveness of diagnostics, vaccines, therapeutics, or other public health measures. The CDC categorizes a SARS-CoV-2 variant with a genetic mutation(s) that is associated with or predicted to have such impacts as a Variant of Interest (VOI). The variant is elevated to the category of Variant of Concern (VOC) if evidence of such deleterious impacts is demonstrated. The four VOC to date are: the Alpha (B.1.1.7) variant originally found in the United Kingdom, the Beta (B.1.351) variant originally found in South Africa, the Gamma (P.1) variant originally found in Japan among travelers from Brazil, and the Delta (B.1.617.2) variant originally found in India.[11] Some of these variants are associated with a 50% or greater increase in transmissibility and/or decreased effectiveness of select combinations of monoclonal antibodies. The proportion of new COVID-19 infections comprised by each variant changes rapidly as new variants emerge in a local region. As of mid-July 2021, Delta has become the dominant lineage throughout the United States and in many countries worldwide.[12,13] Emerging data suggest that Delta is more transmissible than previous VOC, and the United States appears to be entering a fourth surge driven by Delta. Notably, this would be the first surge to occur while COVID-19 vaccines were widely available and correspondingly, these COVID-19 case rates appear highest in states, and particularly counties, with lower vaccination rates. Readers should refer to resources from the CDC for the latest information.

The risk of severe disease or mortality from COVID-19 significantly increases with age. Adults aged 65 years or older represent 80% of COVID-19 deaths in the US and adults 45 years or older represent over 95% of COVID-19 deaths.[14] Male sex is associated with a 3.7 times higher odds of severe disease compared to female sex.[15] Presence of one or more comorbidities is also a predictor of progression to severe COVID-19. In a study of US cases through May 30, 2020, hospitalizations were 6 times higher and deaths were 12 times higher in patients reporting an underlying condition compared to those without a reported underlying condition, with the most common conditions being cardiovascular disease (32%), diabetes (30%), and chronic lung disease (18%).[16] Other comorbidities associated with severe COVID-19 include hypertension, obesity, chronic kidney disease, liver disease, cerebrovascular disease, neurological disorders, immunocompromised states, pregnancy, cancer, smoking, and substance use disorders. Lastly, belonging to specific racial or ethnic groups is associated with a higher risk of severe COVID-19 and mortality.[12,14,15] As of April 21, 2021, Hispanics comprised 37.7% of COVID-19 deaths in the US adjusted for age, while only comprising 19.4% of the US population. A similar trend was also found in non-Hispanic Blacks (22.2% and 12.7%, respectively). In comparison, non-Hispanic Whites comprised 31.8% of COVID-19 deaths adjusted for age while comprising 58.7% of the US population.[17]

The imbalance in the burden of COVID-19 demonstrates health inequities across the US. Understanding and addressing the social determinants of health driving these inequities is a key component of public health efforts to combat COVID-19. Such social determinants include discrimination; poor healthcare access and use; disproportionately higher representation in essential occupations such as farms, factories, grocery stores, public transportation, and healthcare facilities; gaps in education, income, and wealth; and a greater tendency to live in crowded housing.[18]

Pediatric patients are more likely to have asymptomatic or mild COVID-19 illness.[19] Due to the high prevalence of asymptomatic infection in this population, the true incidence of COVID-19 infection is likely underestimated. In one study of children aged 5-17 years diagnosed with COVID-19, 58% reported at least one symptom, 5% reported no symptoms, and symptom data was missing or unknown in the remaining 37%. Only 1.2% of school-aged children required hospitalization, 0.1% required intensive care, and < 0.01% died from COVID-19.[20]

PATHOPHYSIOLOGY

The primary route of transmission of SARS-CoV-2 is direct person-to-person respiratory transmission via infected particles (i.e., droplets and aerosols). Aerosols and droplets containing SARS-CoV-2 are generated from everyday activities, e.g., talking or singing, in addition to coughing and sneezing. Risk of transmission is greatest for individuals in close contact (less than 6 feet apart), for a significant period (greater than 15 minutes), especially while indoors. Thus, physical distancing, face masks, and increased ventilation are all associated with decreased transmission. Hand washing is also a central component of infection prevention. Outdoor transmission is very uncommon, highlighting the importance of adequate ventilation to circulate the surrounding air.[21] Contact with contaminated surfaces or fomites, e.g. doorknobs, clothing, is a rare route of transmission.[22]

Evaluation and management of COVID-19 is based on clinical severity, yet the severity of an individual case often takes days to weeks to become fully evident. This protracted pathophysiology of COVID-19 is a significant driver of both its high infectivity as well as its high morbidity and mortality. The time from virus exposure to symptom onset with COVID-19, i.e. the incubation period, ranges from 2-14 days with a median of 4-5 days.[23,24] One study estimated that 97.5% of patients developed symptoms by 11.5 days from exposure.[24] A patient is deemed presymptomatic if they are infected with SARS-CoV-2 but are not yet experiencing symptoms; infected patients who never experience symptoms are deemed asymptomatic. The majority of COVID-19 transmission (48-62%) may occur from presymptomatic carriers as this is a period early in the disease course (1-3 days prior to symptom onset) when SARS-CoV-2 viral loads are high and patients shed significant amounts of replication-competent virus, but patients do not feel ill.[25] Replication-competent virus has infrequently been recovered greater than 10 days following symptom onset in mild to moderate COVID-19 or greater than 20 days after symptom onset in severe COVID-19.[26] These time periods form the basis of CDC recommendations for isolation and precautions for adults with COVID-19.

COVID-19 disease progression occurs in three phases of increasing severity: (i) early infection, (ii) pulmonary phase, and (iii) hyperinflammation.[27] Notably, not all patients progress through each phase. Early infection is characterized by inoculation, incubation, viral replication, and mild symptoms (e.g., fever, cough, shortness of breath). Following inhalation or other contact with SARS-CoV-2, the virus' spike protein (or S protein) gains entry into the host by binding to angiotensin-converting enzyme-2 (ACE2) receptors present on the surface of cells in the respiratory tract, e.g., nasal and bronchial epithelial cells and alveolar type II pneumocytes. The virus may also directly infect other human epithelial cells expressing ACE2, such as capillary endothelial cells also in the alveoli or endothelial cells in the small intestine. Another receptor, type II cellular transmembrane serine protease (TMPRSS2), is vital to this interaction with ACE2. It activates the spike protein and cleaves ACE2 which allows for fusion of the viral envelope with the host cell membrane and further endocytosis of the spike protein-ACE2 complex. Once inside the cell, viral RNA is released into the cytoplasm and the virus uses host cell machinery to replicate and form new virions, which then bud off the infected host cell via exocytosis or bursting of the host cell. The new virions then travel to infect neighboring cells in the body and/or enter the bloodstream.[8,25,28]

The pulmonary phase is characterized by localized inflammation of the lung with continued viral replication and moderate symptoms. Development of hypoxia, i.e., an oxygen saturation of less than or equal to 94%, is a key sign which is associated with a poorer prognosis and helps determine eligibility for certain therapies. Thus, this second phase can be subdivided into phase IIa without hypoxia and phase IIb with hypoxia.[8] Hypoxia is the result of impaired gas exchange due to alveolar damage from localized pulmonary inflammation. Such inflammation is driven in part by loss of the anti-inflammatory effects of ACE2 on the renin-angiotensin-aldosterone system. Local ACE2 expression is decreased following endocytosis in the form of the SARS-CoV-2 virion-ACE2 complex. Infected endothelial cells also drive local inflammation via activation of innate, cellular, and humoral immune responses. Monocytes and neutrophils are recruited to the site of infection and potent cytokines such as interleukin-6 (IL-6) are released by activated macrophages and other immune cells. Pulmonary infiltration of the immune system in this phase is often recognized as bilateral ground glass opacities and/or consolidations on chest radiograph or computed tomography.[8,25,28]

The third phase of hyperinflammation is characterized by marked systemic inflammation and severe symptoms. The release of high levels of cytokines, sometimes called a “cytokine storm,” leads to dilation of the pulmonary vascular bed with corresponding vascular permeability and leakage, thickening and fibrosis of the alveolar wall, edema filling the alveolar sacs, and thrombus formation (both microthrombi in capillaries and pulmonary emboli in larger vessels of the lungs) which all contribute to pulmonary ischemia and damage. Most COVID-19 deaths are attributable to this cascade leading to acute respiratory distress syndrome (ARDS) with hypoxic respiratory failure. Many critically ill COVID-19 patients also suffer significant injury to one or more additional organ systems, such as the heart, brain, liver, kidneys, and gastrointestinal tract. This may be due to direct cytotoxic injury from the virus given high expression of ACE2 in the endothelial cells of these organs. Organ injury may also be the result of systemic inflammation, cytokine release, and/or thrombosis in local tissues.[8,28] The coagulopathy seen in critically ill patients is a distinct feature of COVID-19 and can appear similar to disseminated intravascular coagulation (DIC).

Most COVID-19 patients recover from illness before progressing to the second or third phase; however, those who do progress and require oxygen supplementation are typically hospitalized. Patients with mild to moderate disease managed in the outpatient setting should be closely monitored, as progression of symptoms to severe disease usually occurs approximately 1 week after initial symptom onset.[29] Among 1.3 million confirmed COVID-19 cases in the U.S from January through May 2020, 14% were hospitalized, 2% required intensive care, and 5% died.[16] A similar spectrum of disease severity was observed among 44,000 confirmed cases in China, with 81% experiencing mild or moderate disease, 14% with severe disease, and 5% with critical illness[30] Among patients hospitalized with COVID-19, the mortality rate is approximately 15% to 20%; yet it can vary widely based on differences in underlying risk factors within the local population, severity of illness, and potentially other factors such as local threshold for hospitalization.[25] In over 20,000 hospitalized patients in the United Kingdom from February through April 2020, mortality risk increased with disease severity: 26% overall, 32% of those in the intensive care unit, and 37% of those on mechanical ventilation.[31] Mortality was even higher, 52% among patients diagnosed with ARDS.[30]

Regarding other potential complications of COVID-19, bacterial co-infection at the time of COVID-19 diagnosis is relatively rare at 3% to 5%.[35] If bacterial co-infection is diagnosed, the causative pathogen is typically *Staphylococcus aureus* or *Streptococcus pneumoniae*.[36] The rate of secondary bacterial infection following presentation is higher at 16%.[35] Secondary invasive fungal infections (e.g., invasive aspergillosis, mucormycosis, and candidiasis) have also been reported in a similar frequency of patients globally, with an increased risk among those with severe illness and/or receiving corticosteroid therapy.[37,38] These data suggest clinicians should remain vigilant for secondary infections and pursue infectious work-up as clinically indicated, particularly in patients with mechanical ventilation, prolonged hospitalizations, and/or immune compromise.

Children and adolescents are at risk of a serious complication termed multisystem inflammatory syndrome in children (MIS-C). MIS-C occurs in the period following acute infection with SARS-CoV-2 and is similar in presentation to Kawasaki disease. The incidence rate is rare and has been estimated to occur in 316 persons per 1,000,000 SARS-CoV-2 infections; however, the true incidence is unknown given the uncertainties surrounding the number of children who have been infected.[39] The syndrome is characterized by a fever, elevated laboratory markers for inflammation, and involvement of two or more organ systems in the presence of current or recent COVID-19 infection or exposure within four weeks and in the absence of alternative plausible diagnoses.[40,41] Sporadic reports of a similar phenomenon in adults, termed multisystem inflammatory syndrome in adults (MIS-A), are also emerging but data are sparse regarding management and treatment.

Long-term sequelae from COVID-19 can include permanent lung injury or other end organ damage (e.g. renal, cardiac, neurologic).[42] Patients with even mild cases of COVID-19 have described neurologic symptoms that have persisted for months following infection, including but not limited to fatigue, self-reported “brain fog” (also described as sluggish or fuzzy cognition), headache, numbness/tingling, dysgeusia, and anosmia.[43] Additional research is needed to further elucidate the impact of COVID-19 on long-term health outcomes among patients. Several health systems in the United States have started a “Post COVID-19 Clinic” or “COVID-19 Long Haul Clinic” to track and manage these patients.

CLINICAL PRESENTATION

CLINICAL PRESENTATION[16,23,29,31-33]

General

- Wide range in clinical presentation and severity from asymptomatic, presymptomatic, mild illness, moderate illness, severe illness, or critical illness which can result in death.

Diagnosis

- Nucleic acid amplification tests (NAATs), such as real-time reverse transcription polymerase chain reaction (RT-PCR), are the gold standard diagnostic tests for COVID-19 infection.
  - NAATs detect the presence of genetic material of SARS-CoV-2 with high sensitivity and specificity, indicating active or recent infection.
  - Most are performed in a laboratory; some are available as point-of-care tests.
  - Limitations include inability to differentiate replicating virus capable of being transmitted to others from nonreplicating virus. Such distinction would require viral culture which is rarely pursued in clinical practice.
- SARS-CoV-2 antigen tests are an alternative diagnostic methodology.
  - These are immunoassays that detect a specific SARS-CoV-2 antigen and indicate active or recent infection.

  - Many are available as point-of-care-tests with results available in minutes, and thus are helpful for screening.
  - Limitations include a lower sensitivity than most NAATs. Confirmatory testing with laboratory-based NAAT is necessary in certain instances (e.g., a patient is symptomatic with a high clinical suspicion for COVID-19, but antigen testing is negative).
- Specimens for NAATs or antigen tests include nasopharyngeal, oropharyngeal, sputum, bronchoalveolar, or saliva samples. Acceptable specimens may vary by the specific test.
- Serologic tests for antibody against SARS-CoV-2 are complementary diagnostics which indicate past infection and/or vaccination.
  - Antibodies can take several days to weeks to develop following infection; thus, serologic tests are generally not useful for diagnosis of active COVID-19 infection.
  - Blood specimens are typically collected via fingerstick or venipuncture for analysis.
- Probable COVID-19 can be diagnosed by presence of a compatible syndrome in either the absence of viral testing or a negative test. False negative tests are most common early in infection.

Signs and Symptoms

- Following viral exposure, initial symptoms take a median of 4 to 5 days to develop and can persist for weeks (or even months, especially in an immune compromised patient)
- Severity of the case may take days to weeks to become fully evident:
  - Median 7 days after initial symptom onset: 40% of patients will progress to feeling short of breath
  - Median 10 days after initial symptom onset: 14% of patients will progress to severe disease and 5% will progress to critical illness
- Most common symptoms, often presenting together:
  - Fever (43-44% at presentation, up to 89% during hospitalization) and/or chills (12%)
  - Cough (50-69%)
  - Shortness of breath or difficulty breathing (19-29%, up to 71% in hospitalized patients)
- Other common symptoms: Fatigue (38%), sputum production (34%), muscle or body aches (15-36%), headache (14-34%), sore throat (14-20%), diarrhea (4-19%), nausea or vomiting (5-12%), abdominal pain (8%), new loss of taste or smell (8%), congestion or runny nose (5-6%)
- Critically ill cases resemble a “cytokine storm” with elevated blood concentrations of interleukin-1 (IL-1), IL-2, IL-6, granulocyte colony stimulating factor (G-CSF), and tumor necrosis factor alpha (TNF alpha), along with elevations of other inflammatory markers

Laboratory Tests

- Comprehensive metabolic panel (e.g., liver function tests elevated in 21%)
- Peripheral blood cell counts often low (e.g., 83% lymphopenia, 34% leukopenia, 36% thrombocytopenia)
- Inflammatory markers are often elevated (e.g., C-reactive protein (elevated in 61%), lactate dehydrogenase (41%), ferritin, creatine kinase (14%))
- Coagulation studies are often abnormal (e.g., D-dimer elevated in 46%)
- Abnormalities become more numerous and pronounced with more severe disease

Other Diagnostic Tests

- Chest radiograph typically performed for patients presenting to the emergency department, computed tomography (CT) typically reserved for hospitalized patients with severe disease
  - Abnormalities including multilobar ground glass opacities (56%), patchy shadowing (52%), or interstitial abnormalities (59% with chest radiograph, 86% with CT)
  - Asymptomatic patients may also have chest abnormalities on imaging
- CT alone is not recommended for screening or first-line diagnosis of COVID-19 due to low specificity and issues related to infection control[34]

PREVENTION

The best way to decrease morbidity and mortality associated with COVID-19 is to prevent infection through vaccination. Face masks, social distancing, and increased ventilation are also effective infection prevention strategies; hand washing and disinfectants may also have a role. Monoclonal antibodies have demonstrated effectiveness for primary prevention or post-exposure prophylaxis of SARS-CoV-2 infection, but these data are preliminary, and they are not currently used in this setting.[44]

Vaccination

SARS-CoV-2 vaccines were developed, distributed globally, and administered to patients within one year of virus identification. The usual timeline from the beginning of pre-clinical work to launch of a successful vaccine is over 10 years, demonstrating the remarkable scientific research efforts for COVID-19 (see Table e132-1).[45]

Table e132-1

Key Points for Covid-19 Vaccines

Type	Vaccine	Manufacturer	Dose	Dosing regimen	When recipients are considered fully protected	Key safety information
mRNA	BNT162b2	Pfizer/BioNTech	0.3 mL	2 dose, day 0 and 21	14 days after dose 2	Rare cases of severe allergic reactions Rare cases of myocarditis, most commonly in males aged 12-29 with second dose
	mRNA1273	Moderna	0.5 mL	2 dose, day 0 and 28	14 days after dose 2	
Adenovirus-vectored	Ad26.CoV2S	Johnson and Johnson	0.5 mL	Single dose	14 days after vaccine	Rare cases of potentially fatal TTS/VITT Ad26.CoV2S associated with rare cases of GBS
	AZD1222	AstraZeneca	0.5 mL	2 dose, day 0 and 28	14 days after dose 2	
Protein subunit + adjuvant	NVX-CoV2372	Novovax	TBD	2 dose, day 0 and 21	14 days after dose 2	

GBS = Guillain-Barre syndrome; TBD = to be determined; TTS = thrombosis with thrombocytopenia syndrome; VITT = vaccine-induced thrombotic thrombocytopenia

This section focuses on the major vaccines used globally as of August 1, 2021. Three vaccines are available in the US under Food and Drug Administration Emergency Use Authorization (FDA EUA): two as a two-dose series using an mRNA technology platform (Pfizer, Moderna) and one as a one-dose injection using an adenovirus vector platform (Johnson & Johnson). A second vaccine using an adenovirus vector platform (Astra Zeneca) is used in many countries globally as a two-dose series, but not in the United States. A protein antigen-based vaccine candidate, NVX-CoV2373, is anticipated to receive US FDA EUA in late 2021. There are multiple inactivated platform vaccines used internationally (e.g., Covaxin, Coronavac, and BBIBP-CorV); however, limited clinical data are publicly available and therefore those vaccines are not discussed in this chapter.

The need for booster doses beyond the currently approved vaccine schedule remains unclear and is currently under investigation. Preliminary real-world evidence suggests the available vaccines have similar efficacy against the currently circulating VOC (Alpha, Beta, Gamma, and Delta) as they do against wild-type virus; however, this is a dynamic situation. Pharmacists and other healthcare providers should reference the CDC for the most recent information regarding COVID-19 vaccines, the need for booster doses, and vaccine efficacy against VOC.[46]

mRNA vaccines

SARS-CoV-2 ushered the first successful mRNA vaccines into widespread use in patients. Although no mRNA vaccines were US FDA-approved prior to COVID-19, the mRNA platform was previously studied in multiple phase 1 and 2 trials for other viruses, which helped accelerate SARS-CoV-2 vaccine development. mRNA vaccines encode the SARS-CoV-2 spike protein, allowing ribosomes within antigen presenting cells to translate the genetic material and present it to the immune system to stimulate an immune response. The mRNA administered is noninfectious and cannot be integrated into human DNA. mRNA is inherently unstable and these vaccines are therefore formulated within lipid nanoparticles to avoid rapid extracellular breakdown.[45] Two mRNA vaccines are currently available globally.

BNT162b2 (Pfizer/BioNtech)

BNT162b2 is an mRNA vaccine that encodes the full length prefusion spike protein for SARS-CoV-2. It received US FDA EUA for patients 12 years of age or older as a two-dose regimen administered on days 0 and 21.[47]

A phase 3 randomized clinical trial (RCT) enrolled 43,448 patients (21,620 vaccine, 21,728 placebo) 16 years of age or older in 152 clinical trial sites worldwide.[6] Patients were randomized to receive two 30 μg doses of BNT162b2 or placebo on day 0 and day 21. The primary efficacy analysis was performed in patients who were seronegative (i.e., patients who did not have antibodies towards SARS-CoV-2) at baseline. The primary endpoint of confirmed symptomatic COVID-19 ≥ 7 days after the second dose occurred in 8/18,198 (0.04%) participants receiving the vaccine compared with 162/18,235 (0.89%) participants receiving placebo for a vaccine efficacy (VE) of 95% (95% CI 90.3 – 97.6%). Only 1 case of severe COVID-19 occurred in a vaccine recipient (compared to 9 cases in placebo recipients), and 0 vaccinated patients required hospitalization.

Adverse events were largely mild to moderate in nature and more likely to occur in younger patients. Systemic reactions were more common after the second dose. Common adverse events were injection site pain (83%), fatigue (59%), headache (52%), myalgia (37%), chills (35%), and fever (16%). Most reactions resolved within 1-2 days after vaccination.

Interim results from an ongoing randomized, placebo-controlled trial of BNT162b2 in adolescents (12 – 15 years of age) demonstrated similar findings. Confirmed COVID-19 ≥ 7 days after the second dose occurred in 16/978 (1.6%) participants who received placebo compared to 0/1,005 (0%) receiving vaccine for an estimated VE of 100% (95% CI 75.3 – 100%). Adverse events in adolescents were similar in frequency and severity to those described above for participants aged 16-25 years.[48]

mRNA1273 (Moderna)

mRNA1273 is an mRNA vaccine that encodes the full length prefusion spike protein for SARS-CoV-2. This vaccine received US FDA EUA as a two-dose regimen administered on days 0 and 28 in adults 18 years of age or older.[49]

A phase 3 trial enrolled approximately 30,000 patients 18 years of age or older to receive two doses of 100 μg mRNA1273 or placebo on day 0 and day 28.[4] The primary efficacy outcome, symptomatic COVID-19 in the per protocol group ≥ 14 days after the second dose, occurred in 11/14,134 (0.08%) participants receiving vaccine compared to 185/14,073 (1.3%) participants receiving placebo, resulting in a VE of 94.1% (95% CI 89.6 – 96.8%). Secondary outcomes included symptomatic COVID-19 ≥ 14 days after the first dose (225 vs. 11 cases; VE 95.2%), and severe disease (0 vs 30 cases in vaccine and placebo recipients, respectively).

Adverse reactions were generally mild to moderate in nature, more common in younger patients, and more frequent and severe following the second dose. After the second dose, injection site reactions were the most common adverse event occurring in 89% of patients, followed by fatigue (65%), myalgia (58%), chills (44%), and fever (16%).

Real-world Safety and Efficacy with mRNA Vaccines

Although not observed in the clinical trials, reports of allergic reactions with administration of both mRNA vaccines surfaced soon after the global vaccination campaign commenced. Ten million doses of BNT162b2 and 7.5 million doses of mRNA1273 were administered to Americans from December 14, 2020, through January 18, 2021, and reported in the CDC vaccine adverse event reporting system (VAERS). Sixty-six cases of anaphylaxis were reported for a rate of 4.7 cases per million doses with BNT162b2 and 2.5 cases per million doses of mRNA1273.[50] In a separate analysis within one health system of 64,900 healthcare workers who received their first dose of an mRNA vaccine, sixteen had an anaphylactic reaction for a rate of 247 cases per million doses.[51] All cases in this series resolved without shock or the need for endotracheal intubation. Ten (63%) of the patients experiencing anaphylactic reaction had a history of prior allergic reactions and 5 (31%) had a history of anaphylaxis. While anaphylaxis is a rare adverse event, it is important to counsel patients prior to vaccination and provide close monitoring for 15-30 minutes after receipt of an mRNA vaccine, especially in patients with a prior history of significant allergic reactions. Pharmacists and patients should also be aware that a delayed (median onset 8 days), large rash at the injection site has been observed following receipt of mRNA1273. These rashes can be managed supportively (ice, antihistamines, topical/systemic corticosteroids) and are not a contraindication to receive subsequent doses of the vaccine, even though they may recur with additional doses.[52] This rash resolves after a median of 6 days.

Real-world evidence has also demonstrated an association between mRNA vaccines (both BNT162b2 and mRNA1273) and myocarditis, more frequently seen with the second dose and in younger males. Median time to symptom (e.g., chest pain, shortness of breath, palpitations) onset is 2 days and occurs within 7 days for most patients. Rates of myocarditis following the second dose are estimated at 40.6 cases per 1 million vaccinations in males aged 12-29, compared to 2.4 cases per 1 million vaccinations in males ≥ 30 years of age. Comparative rates in females are 4.2 and 1 cases per 1 million vaccinations, respectively. The US FDA Advisory Committee on Immunization Practices recommends vaccination in all eligible children, stating the benefit of vaccination outweighs the risk for all age groups.[53]

One important, yet unresolved question from the clinical trials was whether mRNA vaccines prevent asymptomatic infection, a known contributor to the spread of COVID-19. A real-world analysis published by the CDC demonstrated protection against both symptomatic and asymptomatic disease with a VE ≥ 14 days after first dose of 80% (95% CI 59 – 90%), which improved to 90% (95% CI 68 – 97%) 14 days after the second dose.[54] A similar study from the United Kingdom associated vaccination with a 75% reduction in asymptomatic disease.[55] Furthermore, vaccinated participants in this trial who subsequently tested positive for SARS-CoV-2 had lower viral loads when compared to unvaccinated participants. This lower viral burden likely decreases the potential for spreading infection. This is supported by recent evidence from England demonstrating that secondary infection in household members of infected patients occurred 40-50% less frequently when the infected patient was vaccinated.[56] While these data are compelling for protection against asymptomatic infection and subsequent spread of the virus from vaccinated patients, it is critical to stay abreast of the latest CDC recommendations related to post-vaccination infection prevention precautions and counsel patients accordingly.

Viral Vectored Vaccines

Viral vectored vaccines consist of either nonpathogenic or mildly pathogenic adenovirus vectors with altered genetic material to include the SARS-CoV-2 spike protein. The viral vectors are engineered so once the adenovirus enters a human cell, it does not replicate and cause disease; however, the DNA from the vector encoding the spike protein can be synthesized into mRNA. The synthesized mRNA then follows the same process as mRNA vaccines to stimulate an immune response directed toward the SARS-CoV-2 spike protein.

As some adenoviruses can cause human disease, there is a theoretical concern that a patient who has previously been exposed to the vector may have pre-existing immunity to the vector. This pre-existing immunity may neutralize the adenovirus prior to cellular uptake and blunt the development of the immune response against the spike protein. This is of particular concern for a two-dose viral-vectored vaccine schedule given that the recipient has just been exposed to the same adenovirus with dose one. For this reason, some viral vectored vaccines (e.g., the Russian "Sputnik V" COVID-19 vaccine) utilize a heterologous approach where the prime (i.e., first dose) and the subsequent booster doses are developed from different adenovirus vectors.

Ad26.CoV2S (Johnson & Johnson/Janssen)

Ad26.CoV2S is a replication-deficient human adenovirus type 26 vector that expresses a stabilized variant of the full-length SARS-CoV-2 spike protein.[57] This vaccine received US FDA EUA as a single dose in adults 18 years of age or older.[58]

In the phase 3 trial, primary efficacy analyses were performed in 39,321 seronegative patients randomized 1:1 to receive vaccine or placebo, with a median follow up time of 2 months post-vaccination.[7] Vaccination was associated with a significant decrease in the incidence of moderate or severe infection 14 days (116 vs. 348 cases; VE 66.9% (95% CI 59.0 – 73.4)) and 28 days (66 vs. 193 cases; VE 66.1% (95% CI 55.0 – 74.8)) after the dose was administered. Numerically higher rates of efficacy were demonstrated when limited to severe disease cases, and no hospitalizations or deaths related to COVID-19 occurred ≥ 28 days after vaccination. Five deaths related to COVID-19 occurred in the placebo arm.

No benefit on the incidence of asymptomatic infection, assessed by patient serostatus, was observed between day 0 – 29; however, there was a significant decrease in asymptomatic infection between day 29 and 71 post-vaccination (18 vs. 50 cases; VE 66% (95% CI 39.9 – 81.1)). This decrease in asymptomatic infection was consistent with the vaccine efficacy against symptomatic disease.

The most common adverse events were injection site pain (49%), headache (39%), fatigue (38%), and myalgia (33%). Consistent with mRNA vaccines, these occurred less frequently in patients 60 years of age or older. Of note, there was a numerical imbalance (11 vs. 3) in thromboembolic events in vaccinated patients in the trial. Post-marketing surveillance data of nearly 8 million vaccinated Americans identified 28 cases of a potentially life-threatening thrombosis with thrombocytopenia syndrome (TTS), which most commonly presented as cerebral venous sinus thrombosis (CVST). The median onset is 8 (range 6-15) days post-vaccination and appears to occur most frequently in women 18-49 years of age.[59,60] Per the CDC, the estimated incidence of TTS in women aged 18-49 is 7 cases per 1 million vaccinations. While the initial symptoms of CVST may be similar to systemic reactions to vaccination (i.e., severe headache), the timing of the onset of symptoms (1-2 weeks after vaccination with TTS versus 1-2 days after vaccination for systemic reactogenicity symptoms) is an important counseling point for patients. The pathology of TTS appears similar to that described with heparin induced thrombocytopenia and thrombosis, and platelet factor 4 heparin induced thrombocytopenia ELISA antibody tests were positive in all eleven patients tested. Additionally, an association between receipt of Ad26.CoV2S and Guillain-Barré syndrome (GBS) has been demonstrated, with an estimated incidence of 8 cases per 1 million vaccinations. The vaccine is currently recommended to all adults ≥ 18 years of age by the CDC; however, they highlight the importance of counseling females less than 50 years of age on the risk of TTS and the availability of alternative (i.e., mRNA) vaccines. It will be important for pharmacists to monitor this situation and educate patients and providers on warning signs and symptoms of TTS and GBS, as well as the latest recommendations from the FDA and CDC.

AZD1222 (AstraZeneca/Oxford University)

AZD1222 is a replication-deficient chimpanzee adenovirus vector encoded with the full-length spike protein.[61] While the available data suggest vaccine efficacy, the study design and initial data reporting were problematic, hampering public confidence in this vaccine. Rather than performing one large international trial, the investigators initiated several small, similar (yet not identical) trials in different parts of the world. While all trials were randomized and blinded, some of the analyses used placebo as control while some used a meningococcal vaccine as control. Additionally, it was determined after phase 3 trials commenced that a booster vaccine optimized neutralizing antibody response. While this second dose was intended to be given 4 weeks after the initial dose, due to a variety of logistical issues, patients received the booster dose anywhere from 4 to 12 weeks after the initial dose, and there were regional and age differences in patients receiving the booster at different time intervals. Finally, due to a manufacturing error, a substantial number of younger patients in the initial phase 3 trial received a lower dose of viral particles in their first vaccine doses.

The primary efficacy analysis to evaluate incidence of symptomatic COVID-19 ≥ 14 days after the second dose of AZD1222 in baseline seronegative patients was performed for 11,636 volunteers (5,807 vaccine and 5,829 placebo)[5]. The primary outcome occurred in 30 patients receiving vaccine compared with 101 who received placebo (VE 70.4% (95% CI 54.8 – 80.6%)). Similar to mRNA vaccines and Ad26.CoV2S, no patients in the vaccine group experienced hospitalization or death due to COVID-19. Unlike the experience with the aforementioned vaccines, no significant impact was found for developing asymptomatic infection, which occurred in 29/3288 (0.9%) vaccinated patients and 40/3350 (1.2%) receiving placebo (VE 27.3%; 95% CI –17.2 to 54.9).

Detailed safety data were not provided in the publication, however one case of transverse myelitis possibly related to AZD1222 was described. Post-marketing reports suggest an association between AZD1222 and a rare occurrence of vaccine-induced thrombotic thrombocytopenia (VITT) which appears similar in nature to the TTS described with Ad26.CoV2S. Reports from the European Medicines Agency (EMA) and United Kingdom place this adverse event in the range of 8-10 cases per 1 million vaccinations.[62,63] Similar to TTS with Ad26.CoV2S, onset occurs ~1-2 weeks after vaccination, cases predominate in younger females, CVST is the most common presentation, and patients commonly demonstrate positive platelet factor 4 antibody results when tested. It will be important to determine if this rare but serious adverse event is associated with all adenovirus vectored vaccines, as well as what the incidence, mechanisms, and risk factors for TTS and VITT are, so that proper risk/benefit decisions can be made as part of a patient-centered approach to vaccination.

Protein Antigen Adjuvanted Vaccines

NVX-CoV2373 (Novavax)

NVX-CoV2373 consists of a full-length, prefusion stabilized SARS-CoV-2 spike protein antigen adjuvanted with Matrix-M to boost immune response to the spike protein. In a phase 3, randomized, observer blinded, placebo-controlled trial of 14,039 participants in the United Kingdom,[64] patients received two doses of either 5 mcg of NVX-CoV2373 or placebo 21 days apart. Confirmed SARS-CoV-2 infection ≥7 days after the second dose occurred in 10/7,020 (0.1%) participants in the vaccine group compared to 96/7,019 (1.3%) in the placebo arm, for a VE of 89.7% (95% CI 71.3 to 93.5). All five severe cases of COVID-19 occurred in placebo recipients.

Adverse events were more commonly observed in the vaccine group compared to placebo and were more frequently observed after the second dose. Common adverse events included injection site tenderness (76%) and pain (51%), headache (40%), muscle pain (40%), and fatigue (40%). Of note, one case of myocarditis occurred in a vaccine recipient.

A phase 3 clinical trial in the United States and Mexico enrolling 29,960 patients has yet to be published, however, a press release from the NIH stated consistent findings with the UK trial with a VE of 90.4%, and 100% protection against moderate and severe disease. It is anticipated that the company will file for regulatory approval in the United States soon.

TREATMENT

Desired Outcomes and General Approach to Treatment

The US FDA has approved one antiviral agent, remdesivir, for treatment of COVID-19.[65] Other agents that have demonstrated efficacy for COVID-19 include monoclonal antibodies and immunomodulatory therapies (e.g., corticosteroids, tocilizumab, baricitinib). **Table e132-2** outlines which treatments should be considered for each severity stage of COVID-19. Pharmacotherapy employed early in the course of illness (during the early infection and/or pulmonary phases) is focused on minimizing viral replication by either boosting the immune response to eradicate the virus (i.e., monoclonal antibodies) or directly inhibiting viral replication (i.e., remdesivir). If patients progress to more severe stages, characterized by progressive hypoxia, radiographic abnormalities, and/or organ failure, pharmacotherapy employed at these later time points is focused on immune modulation (e.g., corticosteroids, tocilizumab, barcitinib) to help blunt the hyperinflammatory phase which could otherwise cause significant end-organ damage, morbidity, and mortality.

Table e132-2

Treatment Recommendations by Disease Severity and Patient Location

Severity of Illness	Defining Characteristics	Patient Location	Symptom Management	Monoclonal Antibodies	Remdesivir	Corticosteroids	Tocilizumab	Baricitinib	Therapeutic Anticoagulation	Notes

Mild to Moderate, Not Hospitalized	• Not requiring supplemental oxygen above baseline needs	Outpatient or Emergency Department	Yes	Patients at high risk of hospitalization per FDA EUA criteria.	No	No	No	No	No	Patients breathing ambient air should not receive systemic corticosteroids. Trials with inhaled budesonide are ongoing. The role of colchicine, fluvoxamine, and/or ivermectin remain unclear. It is the opinion of the authors that these therapies should not be recommended outside of a clinical trial.
Moderate	• SpO2 >94% breathing ambient air • Radiographic evidence of pneumonia	Hospitalized	Yes	Patients hospitalized for reasons other than COVID-19 and incidentally found to have COVID-19 may be eligible.	Not routinely recommended; consider in high-risk patients.	No	No	No	Insufficient evidence to recommend either for or against use of higher than prophylactic dosing	Patients breathing ambient air should not receive corticosteroids. High-risk patients include profound immunosuppression (e.g. solid organ or hematopoietic cell transplantation, ongoing graft-versus-host-disease, receipt of B-cell depleting therapy with rituximab, ocrelizumab, or ofatumumab, receipt of CAR-T, neutropenia, actively receiving chemotherapy for malignancy, CD4 < 200 cells/mm^3)
Moderate-Severe	• SpO2 ≤ 94% breathing ambient air **not** requiring supplemental oxygen • Radiographic evidence of pneumonia	Hospitalized	Yes	No	Yes	No	No	No	Insufficient evidence to recommend either for or against use of higher than prophylactic dosing	Patients breathing ambient air should not receive corticosteroids.
Severe	• Requiring supplemental oxygen or non-invasive ventilation	Hospitalized	Yes	No	Low-flow O_2: Yes HFNC or NIV: No	Yes	Yes (see notes)	Yes (see notes)	Low-flow O2: Insufficient evidence to recommend either for or against use of higher than standard	Discontinue corticosteroid if supplemental oxygen no longer required. Either tocilizumab or baricitinib should only be

									prophylactic dosing HFNC or NIV: Therapeutic anticoagulation should be avoided unless otherwise indicated for thrombosis treatment	administered in combination with corticosteroids. Benefit has not been established in patients not receiving corticosteroids. Patients should not receive both tocilizumab and baricitinib. Tocilizumab or baricitinib is recommended in patients who have rapidly increasing oxygen needs and require HFNC or NIV and who have significantly increased markers of inflammation (e.g., CRP ≥75 mg/L). The body of evidence supporting tocilizumab use is greater.
Severe-Critical	• Mechanically ventilated, ECMO, septic shock, and/or multiple organ dysfunction	Hospitalized	Yes	No	No	Yes	Yes (see notes)	Yes (see notes)	Therapeutic anticoagulation should be avoided unless otherwise indicated for thrombosis treatment	Large, randomized trials demonstrated no benefit of remdesivir and possible harm of therapeutic anticoagulation in patients requiring mechanical ventilation. Discontinue corticosteroid if supplemental oxygen no longer required. Either tocilizumab or baricitinib should only be administered in combination with corticosteroids. Benefit has not been established in patients not receiving corticosteroids. Patients should not receive both tocilizumab and baricitinib. Tocilizumab or baricitinib are recommended for recently intubated

										patients who have not already received tocilizumab during their admission. The body of evidence supporting tocilizumab use is greater. Current evidence does not support administration >24 hours after intubation.

CAR-T = chimeric antigen receptor T-cell therapy; CRP = C-reactive protein; HFNC = high-flow nasal cannula; NIV = non-invasive ventilation; SpO2 = oxygen saturation.

For those treated in the outpatient setting, the goals of treatment are to prevent progression to severe disease requiring hospitalization and hasten symptom resolution. For those treated in the hospital, the primary goals of therapy are survival, to prevent the need for mechanical ventilation or intensive care unit admission, and to shorten length of hospital stay.

Nonpharmacologic Therapy

Patients infected with SARS-CoV-2 with mild to moderate symptomatic COVID-19 should isolate at home until: (a) symptoms improve, (b) at least 10 days have passed since symptoms appeared, and (c) they are afebrile without use of antipyretic medications for at least 24 hours.[66] Wherever possible, separate rooms, bathrooms, and household items should be used by the infected patient during this time frame, and everyone in the household should remain masked. During this period of isolation, patients are encouraged to monitor their blood oxygen saturation using a home pulse oximeter and seek healthcare if oxygen saturation levels fall to 94% or below. Patients should also seek healthcare if symptoms worsen, especially if breathing becomes more difficult. Adequate sleep, fluid intake, and low levels of activity are encouraged. Symptom control with cough/throat lozenges, warm tea, soup, and non-prescription non-steroidal anti-inflammatory drugs (NSAIDs) or antipyretics (i.e., acetaminophen) are appropriate as needed. Early in the pandemic, NSAIDs were believed to worsen outcomes of patients with COVID-19; however, no data support this claim, contrary data have been published, and the WHO and NIH do not recommend against use of NSAIDs.[33] Similar claims of poor outcomes associated with the use of ACEIs and ARBs have also since been refuted.

Pharmacologic Therapy

The pandemic resulted in an explosion of investigational therapies. There are thousands of clinical trials registered with the US National Library of Medicine under the search term “SARS-CoV-2”. Many pharmacological agents demonstrate potent *in vitro* antiviral activity and/or immunomodulatory properties*;* however, few are subsequently found to be clinically effective in human trials.

Monoclonal Antibodies

Monoclonal antibodies are a form of passive immunity targeting the SARS-CoV-2 spike protein.[67] They neutralize cellular viral entry and recruit immune system effector cells to eradicate virus. Patients with COVID-19 normally seroconvert (i.e., make antibodies) 1-3 weeks post-symptom onset. Importantly, the timing and degree of antibody production can vary amongst patients based on multiple factors, including severity of disease.[68] Monoclonal antibodies are likely to be most effective in patients who have yet to seroconvert or have lower amounts of neutralizing antibodies. Therefore, clinical trial data focus primarily on outpatient use of these agents early in disease to prevent progression to hospitalization or death.

There are currently three anti-SARS-CoV-2 monoclonal antibody combinations available under EUA by the FDA for outpatient use for mild to moderate SARS-CoV-2 infection in patients at high risk for progression of disease: bamlanivimab in combination with etesevimab (BAM-ETE), casirivimab in combination with imdevimab (CAS-IMD), and sotrovimab. While sotrovimab was granted EUA status, it was not purchased or distributed by the US Department of Health and Human Services (HHS) and is only available by direct purchase from the distributor. It will not be discussed in detail in this chapter due to extremely limited availability at this time.

Bamlanivimab and Etesevimab

Bamlanivimab and etesevimab were identified from the serum of convalescent patients. Bamlanivimab is a recombinant neutralizing human IgG1 monoclonal antibody to the receptor binding domain (RBD) of the spike protein of SARS-CoV-2.[69] Etesevimab was selected to be utilized in combination with bamlanivimab based on its binding to different, yet overlapping, epitopes in the RBD and its *in vitro* potency.[70]

BAM-ETE (2800 mg of each) was initially evaluated in a small phase 2 study assessing the impact of BAM-ETE (n = 112) versus placebo (n = 156) on viral load in outpatients with mild-moderate COVID-19.[71] BAM-ETE treatment was associated with a significant reduction in viral load at day 11 when compared to placebo. Importantly, BAM-ETE was also associated with a significant decrease in COVID-19-related hospitalizations or ED visits when compared to placebo (1 event (0.9%) with BAM-ETE compared with 9 events (5.8%) with placebo). There were no serious adverse events reported in patients receiving BAM-ETE that were considered related to the study drug. Two patients had immediate hypersensitivity reactions which were considered mild in severity.

BAM-ETE (2800 mg of each) was then assessed in a phase 3 trial in 1,035 outpatients with mild or moderate COVID-19 who were at high risk for progression to severe disease.[72] The primary outcome of COVID-19-related hospitalization or death from any cause was less frequent in patients receiving BAM-ETE (2.1%) compared to placebo (7.0%). All ten deaths in the study occurred in the placebo arm, including 9 that were considered COVID-19 related. Adverse events were infrequent and similar between groups.

The EUA dose (700 mg bamlanivimab and 1400 mg etesevimab) was selected based on currently unpublished data demonstrating a similar effect as the higher dose on both viral load and progression to hospitalization or death when compared to placebo.[73]

BAM-ETE does not display *in vitro* inhibitory activity against two VOC, Beta and Gamma. On June 25, 2021, the US Department of HHS paused distribution of BAM-ETE due to the high incidence (>10%) of the Gamma variant throughout the US. The pause may be lifted in the future depending on prevalence of circulating variants. Pharmacists are encouraged to monitor the recommendations from the CDC, HHS, NIH, and IDSA related to currently recommended monoclonal antibodies. Notably, the other two antibody products with EUA, casirivimab-imdevimab and sotrovimab, retain *in vitro* inhibitory activity against all currently known VOC.

Casirivimab and imdevimab

Casirivimab and imdevimab are two recombinant human IgG monoclonal antibodies which bind to non-overlapping epitopes of the spike protein RBD of SARS-CoV-2. Like bamlanivimab and etesevimab, they were identified from human convalescent plasma and were selected to be given in combination due to their neutralizing antibody potency, their complementary ability to enhance the antibody effector functions, and ability to prevent the selection of variants.

The safety and efficacy of two different doses of CAS-IMD (1200 mg (600 mg of each) and 2400 mg (1200 mg of each)) were assessed in a phase 3 RCT for the treatment of over 4,000 outpatients with mild-moderate COVID-19 at high risk for disease progression.[74] The primary outcome of COVID-19-related hospitalization or all-cause death by day 28 was significantly reduced with both 1200 mg (1.0% vs. 3.2%; $p = 0.002$) and 2400 mg (1.3% vs. 4.6%; $p < 0.0001$) of CAS-IMD compared to placebo. The median time to symptom resolution was also 4 days shorter with CAS-IMD treatment. Both doses of CAS-IMD were well tolerated, with similar rates of adverse events compared to placebo. Only two hypersensitivity reactions were seen in the cohort, one patient receiving placebo and one receiving the 2400 mg dose of CAS-IMD. Given that both the 1200 mg and 2400 mg displayed similar outcomes in this trial, the current EUA is for a single dose of 1200 mg (600 mg of each).

The phase 2 CAS-IMD data suggested the greatest benefit of monoclonal antibody treatment was in seronegative patients (i.e., those who had not created their own antibodies prior to receiving treatment).[75] Accordingly, the RECOVERY trial investigated the impact of CAS-IMD 8000 mg (4000 mg of each) on 28-day mortality as a function of serostatus (i.e. seropositive versus seronegative) in hospitalized patients with COVID-19.[76] Overall, mortality rates were similar in the CAS-IMD (20%) and placebo (21%) arms. However, when limiting the analysis to those who were seronegative at enrollment, the use of CAS-IMD significantly reduced mortality compared to placebo (24% vs. 30%). To date, the role of CAS-IMD in hospitalized patients has not yet been addressed by the FDA. Currently, the 8,000 mg CAS-IMD dose for seronegative hospitalized patients is only available through the manufacturers compassionate use program, and the EUA remains limited to outpatients with mild-moderate COVID-19 at high risk for disease progression.

Convalescent Plasma

Convalescent plasma (CP) is plasma donated from patients who have recovered from SARS-CoV-2. It is then administered to infected patients with the goal of transferring antibodies to prevent progression of illness and expedite recovery. Convalescent plasma can vary in the amount and type of antibodies that are present in the infused sample. Unfortunately, the composition of the CP administered is either not analyzed or incompletely described in most studies, which makes clinical effectiveness difficult to interpret.

Similar to monoclonal antibodies, the benefit of CP, if one exists, would be greatest if administered early in disease and in the absence of seroconversion. Unfortunately, most trials that evaluated CP in hospitalized patients have demonstrated no benefit. The largest such evaluation, the RECOVERY trial, assessed the impact of CP in over 11,000 hospitalized patients. Mortality was identical (18%) in patients who received CP and untreated controls.

In a small, randomized, placebo-controlled trial in Argentina, early receipt (within 72 hours of symptom onset) of high titer (≥ 1:1000) CP in high-risk elderly patients with mild COVID-19 was associated with a decrease in progression to severe disease (13/80 (16%) patients receiving CP compared to 25/80 (31%) receiving placebo).[77] Conversely, a larger RCT of patients with mild to moderate COVID-19 conducted predominately in the United States evaluating CP to prevent hospitalization or death in high-risk patients presenting to the emergency department within 7 days of symptom onset was stopped early for futility. Given that the preponderance of evidence fails to demonstrate a benefit to treatment, CP is not currently recommended for any population.[32,33]

Remdesivir

Remdesivir (GS-5734™) is an intravenously administered monophosphoramidate prodrug of an adenosine analog.[78] Remdesivir is highly selective for viral polymerases which lowers risk of human toxicity, it has a long intracellular half-life allowing once daily dosing in humans, and it has a high barrier to viral resistance in laboratory studies.[79,80]

The efficacy and safety of remdesivir has been evaluated in 5 randomized, clinical trials demonstrating mixed results.[81-85] The first randomized 236 adult patients with severe COVID-19 to either 10 days of remdesivir or placebo and found no difference in the primary outcome of time to clinical improvement within 28 days after randomization.[81] There was also no difference in death or discharge by day 14, clinical improvement at day 14, time to clinical deterioration, or reduction in viral load. The Adaptive COVID-19 Treatment Trial (ACTT)-1 enrolled 1,063 adult patients with severe COVID-19 to 10 days of remdesivir (N=541) or placebo (N=521).[82] Patients treated with remdesivir experienced shorter time to recovery, defined as either being discharged or ready for discharge, with a risk ratio [RR] for recovery of 1.29 (95% CI 1.12-1.49). The benefit of remdesivir was most pronounced in patients requiring low-flow supplemental oxygen at baseline, where receipt of remdesivir was associated with a 2-day improvement in time to recovery. No benefit was observed in patients breathing ambient air, receiving high-flow supplemental oxygen or noninvasive mechanical ventilation, or requiring mechanical ventilation. The 29-day mortality was 11.4% with remdesivir and 15.2% with placebo (HR 0.73; 95% CI 0.52-1.03).

Remdesivir was studied in an open-label trial of hospitalized patients ≥ 12 years of age with moderate COVID-19 (i.e., patients with pneumonia who were able to maintain oxygen saturation > 94% without supplemental oxygen) and overall, no significant benefit was observed.[84] The trial included 193 patients who received 10 days of remdesivir, 191 who received 5 days or remdesivir, and 200 who continued standard care. On day 11, patients randomized to 5 days of remdesivir had significantly higher odds of a better clinical status than patients receiving standard care; however, there was no difference for patients receiving 10 days of remdesivir which makes results difficult to interpret. Mortality rates were low in all treatment groups.

SIMPLE-1 was a randomized, open-label, multi-center, international trial of 397 patients comparing a 5- or 10-day course of remdesivir for patients with severe COVID-19.[83] After adjustment for differences in baseline clinical status, there was no significant difference between a 5-day and a 10-day course of remdesivir.

A WHO trial of over 5,000 hospitalized patients with COVID-19 (67% receiving supplemental oxygen) demonstrated no difference in in hospital mortality (12.5% vs. 12.7%) between patients receiving remdesivir and standard care.[85] A meta-analysis of all remdesivir randomized trials and remdesivir showed no impact on mortality for hospitalized patients with COVID-19. Accordingly, the WHO guideline on drugs for COVID-19 make a weak recommendation against remdesivir use in all patients, regardless of disease severity.[86] The NIH and IDSA recommend remdesivir use in patients requiring supplemental oxygen or non-invasive ventilation only (i.e., not recommended for mechanically ventilated patients).[32,33] Both recommendations in United States guidelines are driven by the improvements in time to recovery demonstrated in ACTT-1.

Clinical trials and numerous case reports have reinforced the relative safety of remdesivir with most observed adverse events reported as serum aminotransferase elevations, gastrointestinal symptoms, acute kidney injury, and rash. Rates of adverse events reported in trials were similar to rates in patients receiving placebo. It is recommended to not initiate or discontinue remdesivir in patients with alanine aminotransferase (ALT) greater than 10 times the upper limit of normal and signs and symptoms of liver inflammation.[65] However, clinical trials showed similar rates of aminotransferase elevation in remdesivir-treated patients compared to placebo, and therefore liver injury may be an artifact of COVID-19 disease rather than drug-induced. The manufacturer's labeling does not recommend use of remdesivir in patients with eGFR less than 30 mL/minute since these patients were excluded from clinical trials and the drug formulation contains sulfobutylether-beta-cyclodextrin (SBECD), which can accumulate in patients with renal dysfunction. The clinical effects, if any, of SBECD accumulation are poorly described and no patient harm has been associated with SBECD. Remdesivir comes as both a solution and a powder product which contain 6 g SBECD per 100 mg remdesivir and 3 g SBECD per 100 mg remdesivir, respectively. Remdesivir has been used safely in patients with renal dysfunction, including hemodialysis, and therefore use should be considered for patients who may benefit from antiviral therapy regardless of renal function.[87,88]

Remdesivir is FDA approved for hospitalized adults and children 12 years of age and older with COVID-19. Dosing by age and weight is described in **Table e132-3**. Use in children less than 12 years old and in pregnant patients appears to be safe and should be based on clinical judgement if benefit is deemed to outweigh risk.[89-91] It is unknown if remdesivir is present in breast milk and decisions to breastfeed during or immediately following remdesivir therapy should be made on a case-by-case basis.

Table e132-3

Dosing, Monitoring, and Counseling for Drugs with Proven Efficacy for Patients with COVID-19

Drug	Dose	Duration	Drug Interactions	Adverse Events	Treatment pearls
Remdesivir	Adults: 200mg IV on day 1, followed by 100mg IV once daily Pediatric patients 3.5-40 kg: 5mg/kg/dose IV on day 1 (max dose = 200mg), followed by 2.5mg/kg/dose IV once daily (max dose = 100mg)	5 days or until hospital discharge. Guidelines state may extend to 10 days if no substantial improvement by day 5, although data are lacking for this and it is not routinely done in clinical practice.	Chloroquine and hydroxychloroquine may diminish therapeutic effect of remdesivir (Theoretical interaction listed in package insert based on *in vitro* analysis with non-SARS viruses; no clinical data to date to support a clinically relevant impact of coadministration)	ALT > 10x ULN (consider discontinuation), Infusion reaction, Bradycardia, Hypotension	Patients should not be kept in the hospital to complete remdesivir therapy. Patients medically ready for discharge should be discharged. Use lyophilized powder product only for pediatrics (less SBECD, see text).
Dexamethasone	Adults: 6mg IV or orally once daily Pediatrics: 0.15mg/kg orally or IV once daily (max dose = 6mg)	10 days or until hospital discharge or until patient is no longer requiring oxygen support	Moderate CYP3A4 inducer	Hyperglycemia, Fluid retention, Leukocytosis, Dermatologic, Adrenal suppression, Gastrointestinal hemorrhage or perforation, Amyotrophy, Myopathy	Higher doses of 10-20 mg per day were evaluated in smaller trials for patients with severe ARDS; however, these doses are not currently recommended.
Tocilizumab	8mg/kg IV once based on actual body weight (max dose = 800mg)	One dose	May increase metabolism of CYP3A4 substrates Caution with other immunosuppressive therapies	Bacterial infection, Hypersensitivity	Gastrointestinal, hepatic, and hematologic effects seen with prolonged therapy (when used for rheumatoid arthritis)
Bamlanivimab and etesevimab	700mg and 1,400mg IV once	One dose	None	Infusion and local site reactions	Bamlanivimab-etesevimab distribution was paused on June 25, 2021. Sotrovimab is only available for purchase (there is no federally donated supply)
Casirivimab and imdevimab	600mg and 600mg IV once The same dose may be administered as four, 2.5mL subcutaneous injections only when IV is not available. IV route strongly preferred.				
Sotrovimab	500mg IV once				
Baricitinib	4 mg orally daily	14 days or until hospital discharge	Caution with other immunosuppressive therapies	Bacterial infection, Increased aminotransferases, Venous thrombus embolism	

ALT = alanine aminotransferase; ARDS = acute respiratory distress syndrome; IV = intravenous; ULN = upper limit of normal; SBECD = sulfobutylether-beta-cyclodextrin.

Hydroxychloroquine or chloroquine

Chloroquine and hydroxychloroquine are orally administered antimalarial agents with anti-inflammatory and immunomodulatory properties and *in vitro* activity against SARS-CoV-2. Hydroxychloroquine was preferentially considered as a potential treatment option due to a favorable side effect profile over chloroquine.[92] The proposed mechanisms of antiviral activity include pH alterations of intracellular organelles which prevent viral particle release from cells as well as interference with receptor glycosylation, which prevents viral entry.[93] Hundreds of trials were launched to evaluate these agents for prevention and treatment of SARS-CoV-2 infection since these were relatively inexpensive and globally available drugs. Unfortunately, large, randomized trials of pre-exposure prophylaxis, post-exposure prophylaxis, outpatient treatment, and inpatient treatment all demonstrated no benefit of hydroxychloroquine therapy or were halted for futility.[82,85,94-100] The WHO, NIH, and IDSA all make a strong recommendation against hydroxychloroquine (or chloroquine) use in patients with COVID-19.

Azithromycin

Azithromycin is an orally administered macrolide antibiotic that is commonly prescribed acutely for community-acquired pneumonia and chronic obstructive pulmonary disease exacerbations. It is used chronically as an anti-inflammatory agent in patients with cystic fibrosis. After small, controversial pilot studies of poor methodological quality suggested *in vitro* activity and potential *in vivo* efficacy of azithromycin for patients with COVID-19[101,102], it was studied alone and in combination with hydroxychloroquine in several large, randomized trials for treatment of COVID-19.[103,104] No benefit was observed and therefore the NIH and IDSA recommend against use.[32,33]

Lopinavir/ritonavir

Lopinavir is an orally administered human immunodeficiency virus 1 (HIV-1) protease inhibitor administered in combination with ritonavir, a potent CYP3A4 inhibitor which serves to elevate plasma lopinavir concentrations. This drug was repurposed and evaluated for SARS-CoV-1 and MERS-CoV with conflicting results. When compared to standard care in hospitalized patients with COVID-19, lopinavir / ritonavir showed no difference in time to clinical improvement, mortality, or percentage of patients with detectable viral RNA at various time points between groups.[105] In the RECOVERY trial, treatment with lopinavir / ritonavir was not associated with decreased hospital length of stay, progression to mechanical ventilation, or death at 28 days.[106] Finally, there was no difference in in-hospital mortality in the WHO Solidarity trial when lopinavir was compared to standard care for COVID-19.[107] Based on the results of these trials, the WHO, NIH, and IDSA all make strong recommendations against the use of lopinavir / ritonavir in patients with COVID-19.

Ivermectin

Ivermectin is an orally administered antihelmintic agent used globally for treatment of onchocerciasis, Strongyloidiasis, and scabies, that has *in vitro* activity against several RNA viruses including SARS-CoV-2.[108,109] The proposed mechanism of action is binding to importin α/β1 heterodimer, a nuclear transport protein, and subsequent prevention of viral proteins from entering cell nuclei.[109] Human pharmacokinetic models demonstrate drug concentrations achieved in lung and plasma are much lower than the concentration required for *in vitro* inhibition, making it unlikely ivermectin would be clinically effective.[110] Despite these pharmacokinetic concerns, ivermectin has been evaluated in several observational and a few small, randomized trials for patients with COVID-19, with mixed results.[111] Most studies reporting benefit of ivermectin are only available in pre-print (i.e., have not undergone peer review) and have significant methodological flaws, making them difficult to interpret. Published randomized trial data comparing patients with mild COVID-19 who received ivermectin or placebo found no difference in time to symptom resolution or in prevention of hospitalization.[112,113] The NIH states there are insufficient data to recommend either for or against the use of ivermectin for treatment of COVID-19; the IDSA suggests against use outside the context of a clinical trial.[32,33]

Corticosteroids

There was significant interest in and controversy surrounding corticosteroids for severe COVID-19 at the beginning of the pandemic. This stemmed from the evolving understanding of the hyperinflammatory pathogenesis in severe COVID-19 and the potential role of corticosteroids to blunt this pathway juxtaposed with data from patients with SARS-CoV-1 and MERS-CoV suggesting administration of corticosteroids was associated with delayed viral clearance and potentially worse outcomes. Importantly, all data in SARS-CoV-1 and MERS-CoV were from small, observational analyses with significant limitations and biases including confounding by indication (i.e., sicker patients tend to be treated with steroids). Thus, these data for corticosteroids in previous coronavirus infections were largely uninterpretable and uninformative.

The RECOVERY trial compared dexamethasone 6 mg either by mouth or intravenously for up to 10 days in addition to standard care versus standard care alone for the treatment of over 6,000 hospitalized patients with COVID-19.[114] 28-day mortality was lower (22.9%) in patients receiving dexamethasone compared to those receiving standard care alone (25.7%) (RR 0.83, 95% CI 0.75 – 0.93). Dexamethasone demonstrated the largest impact on 28-day mortality in patients who were receiving invasive mechanical ventilation at baseline (29.3% vs 41.4%: RR 0.64, 95% CI 0.51 – 0.81). A mortality benefit was also demonstrated in patients requiring supplemental oxygen at baseline (23.3% vs. 26.2%). There was no benefit seen in patients not requiring supplemental oxygen at baseline. There were no major safety concerns were noted in patients receiving dexamethasone.

Other randomized controlled trials assessing various corticosteroids and dosing regimens were stopped once the results from RECOVERY were announced, since it would be unethical to continue to randomize patients to not receive corticosteroids. A meta-analysis of all clinical trials (including RECOVERY) in critically ill patients receiving corticosteroids confirmed a mortality benefit (Odds Ratio for death 0.66, 95% CI 0.53 – 0.82) regardless of corticosteroid administered, dose utilized, or degree of oxygen requirement at baseline.[115] Treatment guidelines currently recommend dexamethasone 6 mg for up to ten days for the management of hospitalized patients with COVID-19 requiring oxygen support. Corticosteroids are not recommended if patients do not require supplemental oxygen as there is concern for potential harm in that subset. Furthermore, it is unclear if systemic corticosteroids have a role in outpatient management of COVID-19 and should not be used in this patient population outside of a clinical trial.

Inhaled budesonide has been evaluated in multiple trials for outpatients with mild COVID-19 and may be associated with reduced time to clinical recovery and less need for medical visits.[116,117] Further data are needed to determine the role in therapy of inhaled corticosteroid therapy in outpatients.

Interleukin-6 receptor antagonists

Tocilizumab is a humanized interleukin-6 receptor antagonist (IL-6ra) monoclonal antibody FDA-approved for severe rheumatoid arthritis, systemic juvenile idiopathic arthritis, giant cell arteritis, and life-threatening cytokine release syndrome induced by chimeric antigen receptor (CAR) T-cell therapy.[118] Sarilumab is another IL-6ra FDA-approved for rheumatoid arthritis. Tocilizumab was evaluated in multiple RCTs for treatment of severe COVID-19 after an early case series described a hyperinflammatory state in COVID-19 patients and improved clinical outcomes with tocilizumab use.[119] Early trials found no overall benefit to tocilizumab treatment, but these results were limited by inconsistent corticosteroid use, varying severity of illness in patients enrolled, uncontrolled timing of tocilizumab administration, and small sample sizes.[120-124] The REMAP-CAP trial enrolled critically ill patients within 24 hours of new requirement of respiratory or cardiovascular support to receive tocilizumab, sarilumab, or standard care.[125] The primary outcome of days free of organ support and in-hospital mortality was significantly improved in patients receiving IL-6ra compared to standard care. Mortality and progression to intubation or death were also significantly lower in tocilizumab and sarilumab-treated patients. Tocilizumab and sarilumab were equally effective.[125] Greater than 80% of the patients in this study received corticosteroids, demonstrating the incremental benefit of IL-6 immunomodulation in addition to corticosteroids, which had been lacking from previous trials.

The RECOVERY trial compared tocilizumab to standard care in over 4,000 patients with oxygen saturation less than 92% breathing ambient air or requiring any form of oxygen supplementation and evidence of hyperinflammation (i.e., C reactive protein ≥ 75 mg/L).[126] 82% of patients in each treatment arm received concomitant corticosteroids. Tocilizumab-treated patients had significantly lower mortality at day 28 (31% vs. 35%). Based on these two large trials, the NIH and the IDSA recommend tocilizumab in addition to dexamethasone for patients with rapidly increasing oxygen requirements and significantly increased inflammatory markers, and the US FDA granted EUA.[32,33,127] A large meta-analysis by the WHO of nearly 11,000 patients from 27 trials recently confirmed that IL-6ra treatment is associated with lower 28-day all-cause mortality compared to usual care or placebo.[128] The totality of evidence is more robust for use of tocilizumab for severe COVID-19; however, sarilumab may be an acceptable alternative if tocilizumab is unavailable.

Baricitinib

Baricitinib is an orally administered Janus kinase (JAK)-1 and JAK-2 inhibitor that mitigates inflammation and is FDA-approved for treatment of rheumatoid arthritis. It may display antiviral activity by inhibiting viral endocytosis and prevent viral entry into human cells. Baricitinib plus remdesivir therapy (Adaptive COVID-19 Treatment Trial (i.e., ACTT-2)) resulted in a faster median time to recovery than placebo plus remdesivir (median 7 days vs. 8 days in hospitalized patients with COVID-19).[129] There was no difference in mortality, but receipt of baricitinib was associated with a decrease in progression to mechanical ventilation or death. A minority of patients in this trial received corticosteroids, making the results difficult to interpret in the context of standard care by the time the results were published. Adverse events were similar between groups.

A later, global trial (COV-BARRIER) of baricitinib versus placebo plus standard care (79% received corticosteroids) in hospitalized patients found no difference in progression to severe disease or clinical improvement by day 28, but lower 28- and 60-day mortality in baricitinib-treated patients.[130] The FDA issued an EUA on November 19, 2020 allowing use of baricitinib in hospitalized patients aged 2 years or older who require oxygen supplementation of any form.[131] The NIH guidelines recommend baricitinib or tocilizumab in addition to dexamethasone for hospitalized patients with rapidly increasing oxygen needs and systemic inflammation.[33] There is more evidence supporting use of tocilizumab in this patient population; however, baricitinib is an appropriate alternative if tocilizumab is unavailable.

Anticoagulation

Patients with severe COVID-19 often have prothrombotic abnormalities including elevated D-dimer, fibrinogen, and factor VIII along with decreased protein C, protein S, and antithrombin levels.[132,133] In addition to a systemic inflammatory response, SARS-CoV-2 binding to ACE-2 receptors can result in endothelial injury and thrombosis. While risk of a venous thromboembolism (VTE) is high in critically ill patients at baseline, it is unknown if patients with COVID-19 are at increased risk compared to other patients with acute illness. Given these unknowns, clinical trials sought to compare the safety and efficacy of higher doses of anticoagulants to standard prophylaxis doses in patients with COVID-19.

A trial that randomized 600 intensive care unit patients to "intermediate dose" enoxaparin prophylaxis (i.e, 1 mg/kg subcutaneously daily) versus standard enoxaparin prophylaxis (i.e., 40 mg subcutaneously daily) found no difference in mortality or VTE events, but more bleeding and thrombocytopenia in the intermediate dose group.[134] A separate randomized trial of critically ill patients comparing empiric therapeutic anticoagulation (i.e., in the absence of a documented VTE) to standard VTE prophylaxis was halted for futility and a potential of harm due to increased rates of bleeding in patients receiving therapeutic dosing.[135] However, empiric therapeutic anticoagulation was beneficial in this same trial for moderately ill patients (i.e., patients not requiring organ support) regardless of D dimer.[136] A separate trial enrolled moderately ill hospitalized patients only with elevated D dimers; therapeutic enoxaparin was not associated with a decrease in the composite endpoint of death, invasive mechanical ventilation, non-invasive mechanical ventilation or ICU admission; however, it was associated with lower all-cause mortality at day 28 compared to prophylactic heparin (1.8% vs 7.6%) with similar rates of major bleeding.[137] Adding to the mixed results, rivaroxaban treatment was not associated with improved clinical outcomes and was associated with more bleeding compared with prophylactic heparin in a similar patient population.[138]

At this time, the NIH states there is insufficient evidence to recommend either for or against the use of higher than prophylactic dosing of anticoagulation for VTE prophylaxis in hospitalized patients with COVID-19. If empiric therapeutic anticoagulation is used, enoxaparin is recommended. Hospitalized patients with COVID-19 should, at a minimum, receive standard VTE prophylaxis.

An evaluation of post-discharge VTE data compared patients with COVID-19 to patients without COVID-19 and found no difference in odds of VTE within 42 days of discharge (OR 1.6; 95% CI 0.77-3.1).[139] Hospitalized patients should not be routinely discharged on VTE prophylaxis outside the context of a clinical trial. It may be reasonable to discharge patients at low risk for bleeding and high risk for VTE on extended VTE prophylaxis per protocols for patients without COVID-19.[140,141] This is reflected in the NIH guidelines which recommend no anticoagulation for mild-moderately ill outpatients with COVID-19, except in the context of a clinical trial.[33]

Colchicine

Colchicine is an oral, anti-inflammatory drug used commonly for gout and pericarditis. In patients 40 years or older with mild to moderate COVID-19 and at high risk for severe disease, there was no difference between 30 days of colchicine (0.5 mg by mouth twice daily x 3 days, then daily for 27 days) or placebo in a composite endpoint of hospitalizations or death (4.7% colchicine vs. 5.8% placebo) (COLCORONA trial).[142] However, in the subgroup of patients only with PCR-confirmed COVID-19 there was a significant benefit with colchicine (4.6% vs. 6%). On balance, significantly more patients experienced pulmonary embolism (0.5% vs. 0.1%) and diarrhea (13.7% vs. 7.3%) in the colchicine-treated group. Conversely, the RECOVERY trial halted enrollment of hospitalized patients to receive colchicine vs. standard care due to futility.[143] The current role of colchicine in the treatment of COVID-19, if any, remains unclear, and it is not currently recommended in any national treatment guideline.

Fluvoxamine

Fluvoxamine is a selective serotonin reuptake inhibitor (SSRI) with high affinity for the σ-1 receptor (SIR). The SIR is a protein involved in cytokine production regulation, and agonism may reduce damaging inflammatory responses. In one small randomized clinical trial of mild to moderately ill outpatients with COVID-19, clinical deterioration was significantly less frequent in fluvoxamine treated patients (dose-escalated regimen up to 100 mg by mouth three times daily through day 15) compared to placebo (0% vs 8.3%).[144] Other larger trials are enrolling, and fluvoxamine is not recommended for use outside of the context of a clinical trial.

Supplements

Nonprescription supplements including, but not limited to, vitamin D, vitamin C, vitamin K, zinc, and melatonin have all been evaluated for prevention and treatment of COVID-19.[145] No supplement has demonstrated benefit and should not be recommended outside of the context of a clinical trial. Supplements are unlikely to cause harm if used at standard doses.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitor for resolution of signs and symptoms (e.g., hypoxia, fever, cough, shortness of breath). Also monitor for any adverse events while on therapy (e.g., transaminitis while on remdesivir; hyperglycemia, neurological sides effects, secondary infections, etc. while on corticosteroids). Report any adverse events while on with medication therapy to FDA MedWatch program and any adverse events following vaccine administration to FDA Vaccine Adverse Event Reporting System (VAERS), especially if serious or previously unreported. If patient improves such that they are no longer eligible for a specific therapy (e.g., on dexamethasone, yet no longer requiring supplemental oxygen), be sure to modify or discontinue therapy as needed. Upon resolution of their illness, encourage preventive measures such as vaccination, wearing a mask, social distancing, increased ventilation, and handwashing for the patient, their family, and/or other members of their household.

CONCLUSIONS

It is important to pause and reflect on key lessons learned from the Covid-19 pandemic. Perhaps the most notable is the importance of following evidence-based medicine when considering therapeutic options for patients. While it can be difficult to withhold readily available therapies that may be considered low risk for patients, SARS-CoV-2 has re-emphasized the need to prioritize enrollment into randomized clinical trials to robustly assess if therapies are effective. Patients were given millions of doses of ineffective medications throughout the pandemic which led not only to unnecessary adverse events, but also delayed identification of therapeutic solutions. To date, only a handful of therapies have proven efficacious for the treatment of COVID-19, and prevention through vaccination and non-pharmacologic interventions remain paramount. Importantly, prevention and management of SARS-CoV-2 are rapidly dynamic areas and students are encouraged to reference the recommendations and guidance from the NIH, IDSA, and CDC for the latest information.

LIST OF ABBREVIATIONS USED

ALT: Alanine Aminotransferase

CP: Convalescent Plasma

CT: Computed Tomography

CVST: Cerebral Venous Sinus Thrombosis

EMA: European Medicines Agency

MIS-C: Multisystem Inflammatory Syndrome in Children

RBD: Receptor Binding Domain

SBECD: Sulfobutylether-beta-Cyclodextrin

TTS: Thrombosis with Thrombocytopenia Syndrome

ULN: Upper limit of normal

VAERS: Vaccine Adverse Event Reporting System

VE: Vaccine Efficacy

VITT: Vaccine-Induced Thrombotic Thrombocytopenia

VOC: Variant of Concern

VOI: Variant of Interest

VTE: Venous Thromboembolism

SELF-ASSESSMENT QUESTIONS

1. In which “phase” of COVID-19 are antiviral therapies most likely to be effective

a. Early infection

b. Pulmonary Phase

c. Hyperinflammatory Phase

d. There is no role for antiviral therapy in COVID-19

2. Which of the following risk factors has the greatest association with death from COVID-19?

a. Male sex

b. Diabetes

c. Age ≥ 65

d. History of COVID-19

3. What is the most common characteristic to date of the SARS-CoV-2 variants of concern (VOC)?

a. More severe disease

b. Enhanced transmission

c. Remdesivir resistance

d. Decreased efficacy of vaccines

4. Which of the following patients is most likely to have a systemic reactogenicity reaction (e.g., headache, myalgias) to an mRNA vaccine?

a. 22-year-old male receiving dose 2

b. 68-year-old female receiving dose 1

c. 35-year-old male receiving dose 1

d. 77-year-old female receiving dose 2

5. Which of the following patients is at highest risk for myocarditis following an MRNA vaccine?

a. 63-year-old male with a history of congestive heart failure

b. 12-year-old female who plays soccer

c. 19-year-old male in a college marching band

d. 78-year-old female with a history of viral myocarditis

6. A patient comes into the pharmacy and asks about the ability of the BNT162b2 (Pfizer) vaccine to prevent asymptomatic infection. Which of the following is the most accurate response?

a. Data are lacking regarding ability of BNT162b2 to prevent asymptomatic infection, but other vaccines are effective.

b. Real world evidence suggests BNT162b2 significantly decreases the risk of asymptomatic infection by 98%.

c. Emerging data suggest mRNA vaccines are effective in decreasing asymptomatic infection and those who are infected have lower viral loads for shorter periods of time.

d. Data are still unavailable assessing the impact of vaccines on asymptomatic infection, however randomized controlled trials are ongoing.

7. Which of the following patients is at greatest risk for thrombosis with thrombocytopenia syndrome (TTS) with Ad26.CoV2S (Johnson & Johnson)?

a. 30-year-old male with history of spontaneous subarachnoid hemorrhage

b. 38-year-old female with no significant past medical history

c. 68-year-old female with history of multiple venous thromboembolic events

d. 55-year-old man with congestive heart failure and atrial fibrillation receiving warfarin

8. Which of the following therapies does not display *in vitro* inhibitory activity against the Gamma Variant?

a. Bamlanivimab - Etesevimab

b. Sotrovimab

c. Remdesivir

d. Casirivimab - Imdevimab

9. Which of the following patients is most appropriate for convalescent plasma treatment?

a. 42-year-old female presenting to the emergency department with moderate COVID-19 and symptom onset 11 days ago.

b. 78-year-old male presenting to his primary care physician's clinic, experiencing only fever, symptom onset 1 day ago

c. 65-year-old male mechanically ventilated in the intensive care unit who has failed therapy with remdesivir, dexamethasone, and tocilizumab

d. Convalescent plasma is not recommended for any patient with COVID-19 outside of a clinical trial

10. JG is a 44-year-old male admitted to hospital with COVID-19. He has a new oxygen requirement of 3L via nasal cannula and was started on remdesivir. By day 3,his fever resolved and he is breathing ambient air. What is the best course of action for completing his course of remdesivir?

a. He should remain in the hospital for 2 more days to complete a 5-day course, as this was the minimally effective duration demonstrated in the clinical trials

b. JG should be discharged from the hospital and 2 days of remdesivir should be administered in the outpatient setting via a home infusion company

c. JG should be discharged and remdesivir should be discontinued

d. JG should be discharged on oral oseltamivir to complete 2 more days of antiviral therapy

11. Which of the following laboratory values should be monitored for patients receiving remdesivir?

a. Creatinine kinase

b. Potassium

c. Liver function tests

d. Blood glucose

12. What COVID-19 patient listed below is most likely to benefit from tocilizumab treatment?

a. A patient in the hyperinflammatory phase who was placed on mechanical ventilation a week ago, but has failed to improve

b. A patient who was recently admitted to a medical ward, is currently only receiving remdesivir for COIVD-19 management, and has had an increase in their oxygen needs from room air to 6L via nasal cannula

c. A patient presenting to the emergency department with an elevated IL-6 serum concentration

d. A patient receiving remdesivir and dexamethasone on a medical ward who has an elevated CRP level and new, rapidly increasing oxygen requirements

13. A 68-year-old female with COVID-19 is admitted to the medical ward. She has extensive comorbidities but is doing relatively well with just a fever (39.4 degrees Celsius) and is saturating 98% on room air. The medical intern wants to start dexamethasone, what is the most appropriate response.

a. Dexamethasone is inappropriate in this patient, given that she is not requiring supplemental oxygen, and a benefit in this type of patient has not been demonstrated.

b. Dexamethasone should be started ASAP, as it has consistently demonstrated a mortality benefit in hospitalized patients with COVID-19.

c. Dexamethasone should be started with either tocilizumab or baricitinib as soon as possible.

d. Dexamethasone is appropriate, but it should not be administered without giving remdesivir as well

14. EM is a 31-year-old female with morbid obesity presenting to her primary care physician with a cough and fever for 2 days. She tests positive for COVID-19. What is the best recommended treatment for EM at this time?

a. Fluvoxamine and monoclonal antibody

b. Colchicine and monoclonal antibody

c. Zinc and monoclonal antibody

d. Supportive care and monoclonal antibody

15. JP is a 41-year-old male (169 kg) admitted to the medical intensive care unit. He was diagnosed 12 days ago with COVID-19. After spending 5 days at home, he presented to the Emergency Department with worsening dyspnea and fever. Now, on day 7 of hospitalization, he acutely worsened and required mechanical ventilation. He is receiving dexamethasone 6mg IV every 24 hours (day 7 of steroid treatment) and recently completed 5 days of remdesivir. Baricitinib is not on your hospital formulary. What is the best treatment for JP now?

a. Give tocilizumab 1,350mg IV once and increase dexamethasone to 10mg IV twice daily

b. Give tocilizumab 800mg IV once and increase dexamethasone to 10mg IV twice daily

c. Give tocilizumab 1,350mg IV once and continue dexamethasone 6mg IV daily

d. Give tocilizumab 800mg IV once and continue dexamethasone 6mg IV daily

SELF-ASSESSMENT QUESTION ANSWERS

1. **A.** Viral replication is highest early in infection. While viral replication can occur throughout the pulmonary phase, progression of illness in this phase is driven by localized pulmonary inflammation and hypoxia and anti-inflammatory therapies (i.e., dexamethasone) improve mortality in these patients. Therapies directly targeting the virus (i.e., monoclonal antibodies, remdesivir) are most effective early in the course of illness to prevent progression of illness. [Pathophysiology section; Monoclonal antibodies and remdesivir sections]

2. **C.** Greater than 80% of deaths and ~50% of hospitalizations for COVID-19 occur in patients ≥ 65 years of age. While males and patients with certain comorbidities (including diabetes) are at greater risk for severe disease, the association between advanced age and death is strongest. [Etiology and Epidemiology Section]. Reinfection in patients with a history of COVID-19 remains rare, and there is no indication that it is associated with more severe disease or death.

3. **B.** All variants of concern (VOC) to date have been associated with some degree of enhanced transmission. The Delta variant has the greatest association [Etiology and Epidemiology Section]. While there is concern for more severe disease and immune evasion with VOCs, current evidence does not support this. Mutations to the spike protein are common in VOC; however, this would not be expected to impact the activity of remdesivir, which inhibits SARS-CoV-2 polymerase. Finally, available data suggest vaccines are effective against all VOC as of July 2021.

4. **A.** Younger patients (≤ 55 years of age) are more likely to have systemic reactogenicity reactions than older adults, and it the frequency increases with the second dose [mRNA vaccine section].

5. **C.** Rates of myocarditis are highest in males aged 12-29 with mRNA vaccines. Rates in males ≥ 30 or females are over ten times less frequent [real world safety and efficacy of mRNA vaccines].

6. **C.** mRNA vaccines are effective in decreasing asymptomatic infection (≥75 %), and in those infected they have lower viral loads, are positive for shorter periods of time, and are less likely to transmit the virus to those in their household [real world safety and efficacy of mRNA vaccines].

7. **B.** TTS has most frequently been demonstrated in females aged 18-49. This is no association with other comorbidities and/or with male patients [Ad26.CoV2S section].

8. **A.** Bamlanivimab-etesevimab does not have in vitro inhibitory activity against the Beta and Gamma variants. The other two mAb options (casirivimab-imdevimab and sotrovimab) retain activity against all current VOC. Remdesivir inhibits viral polymerase, and thus is not impacted by mutations in the spike protein [monoclonal antibody section].

9. **D.** Convalescent Plasma is not currently recommended for any patient with COVID-19 by any international guideline [Convalescent Plasma section].

10. **B.** A patient should not be kept in hospital to complete a course of remdesivir. In the ACTT-1 trial, which was the only placebo-controlled study to demonstrate a benefit of remdesivir, patients were not required to stay in hospital to complete their course. Furthermore, the benefit of remdesivir, if one exists, is in decreasing the length of stay, and keeping a patient in the hospital to complete their course of therapy would therefore defeat the purpose [remdesivir section].

11. **C.** Although well tolerated in the clinical trials, remdesivir has been associated with elevations in aminotransferases in phase 1 studies and per the package insert, consideration should be given for discontinuation if ALT is greater than 10 times the upper limit of normal.

12. **D.** Patient D has all of the characteristics of patients who benefitted most from tocilizumab in the clinical trials. Patient A is unlikely to have benefit given that they have been on the ventilator for a week, and the benefit of tocilizumab is likely lost at that point. While patient B has worsening oxygen status, they are not receiving dexamethasone, and tocilizumab has only been proven to be efficacious when added to corticosteroids. This patient could benefit from initiation of dexamethasone and then consideration could be given to the addition of tocilizumab at that point. To date, no association has been demonstrated with serum IL-6 concentration and effect of tocilizumab, so that laboratory value alone would not be an indication for tocilizumab in patient C.

13. **A.** Data do not currently exist suggesting a benefit in a patient not requiring supplemental oxygen, and the RECOVERY trial hinted at possible harm in this population.

14. **D.** Monoclonal antibody (mAb) treatment is associated with decreased hospitalizations and deaths in outpatients with mild-moderate COVID-19, within 7 days of symptom onset, and a risk factor for progression to severe illness. This patient's morbid obesity puts them at risk for severe disease, and they are early enough in disease that mAbs are beneficial. There is no benefit to any other outpatient treatment other than supportive care.

15. **D.** The maximum dose of tocilizumab is 800mg. Answers A and C are incorrect because this doses tocilizumab on the patient's total body weight without the dose cap. There are no data to support increasing the dose of dexamethasone, so answer B is also incorrect.

DiPiro's Pharmacotherapy: A Pathophysiologic Approach, 12e >

Chapter e138: Parasitic Diseases

Alireza FakhriRavari; Elizabeth Markelz; Jason M. Cota

KEY CONCEPTS

KEY CONCEPTS

① Single-dose tinidazole is the preferred treatment for giardiasis treatment.

② HIV-infected patients with cryptosporidiosis must receive antiretroviral therapy as the mainstay of therapy in addition to antiparasitic therapy.

③ *Entamoeba histolytica*-specific immunoassays are required to diagnose amebiasis because stool sample microscopy does not distinguish between *E. histolytica* and the nonpathogenic *Entamoeba*.

④ Metronidazole and tinidazole are tissue-acting agents against *Entamoeba*, whereas paromomycin and iodoquinol are luminal amebicides.

⑤ Benznidazole is recommended for treatment of Chagas disease in all patients without established cardiomyopathy.

⑥ Atovaquone and azithromycin combination therapy is recommended for treatment of babesiosis.

⑦ Patients with noncalcified parenchymal neurocysticercosis should initially receive symptomatic therapy with corticosteroids and antiepileptic drugs followed by antihelminthic therapy.

⑧ For head lice, either nonprescription 1% permethrin or pyrethrins plus piperonyl butoxide topical preparations are agents of choice unless local resistance to these agents is documented.

⑨ A single application of 5% permethrin results in cure rates in more than 90% of subjects with scabies at 14 and 28 days, but a second dose should be applied 1 week later because its ovicidal efficacy remains unclear.

⑩ Chemoprophylaxis with non-chloroquine antimalarial drugs such as atovaquone-proguanil and doxycycline retain effectiveness in areas where chloroquine-resistant *Plasmodium falciparum* exposure is likely.

BEYOND THE BOOK

BEYOND THE BOOK

Review the figures depicting the life cycle of each of the following parasites on the Centers for Disease Control and Prevention (CDC) Website. Identify the primary way in which each parasite enters the human host and propose at least one strategy to prevent infection from that parasite. The parasites below are listed in order of least to most complex life cycle.

Head Lice (https://www.cdc.gov/parasites/lice/head/biology.html)

Giardiasis (https://www.cdc.gov/parasites/giardia/pathogen.html)

Cryptosporidiosis (https://www.cdc.gov/parasites/crypto/pathogen.html)

Cysticercosis (https://www.cdc.gov/parasites/cysticercosis/biology.html)

Chagas Disease (https://www.cdc.gov/parasites/chagas/biology.html)

Malaria (https://www.cdc.gov/dpdx/malaria/)

This activity is intended to help learners propose risk factors for parasitic infections and nonpharmacologic measures that can be implemented to prevent disease transmission.

INTRODUCTION

Parasitic diseases remain a significant global health problem causing approximately 1 million deaths per year and affecting more than 1.7 billion people worldwide.[1-4] In the United States, immunocompromised patients, ethnic/racial minorities, immigrants, those with recent travel to developing regions, individuals living in poor sanitary conditions, and people who lack access to basic healthcare services appear to be at the highest risk for developing parasitic diseases.[5,6] However, people in every income and social strata can become infected. In fact, the CDC has referred to five diseases as neglected parasitic infections and has prioritized these for increased public health action.[6] They include Chagas disease, cysticercosis, toxocariasis, toxoplasmosis, and trichomoniasis.

Host–Parasite Relationship

General prevention and treatment principles of parasitic infections are based on the host–parasite relationship. *Symbiosis* describes an essential biological relationship between two species. *Parasitism* is a symbiotic relationship in which one species (the host) is injured through the activities of the other (the parasite). The life cycle of a parasite may occur solely in human hosts or in one or more hosts before it causes human disease. *Definitive hosts* are those in which parasites undergo sexual reproduction; whereas *intermediate hosts* allow larval or asexual stages of development to occur. Determining what part of a parasite's life cycle occurs in human hosts is important for antiparasitic drug development.

Vectors, which may also serve as definitive or intermediate hosts, are responsible for transferring a parasite to another host. An example would be the *Anopheles* mosquito that harbors and supports reproduction of the parasite *Plasmodium*. In turn, the infected mosquito can transmit the malaria-causing parasite to a human host through a bite. Reducing human exposure to those vectors responsible for human disease becomes an important nonpharmacologic public health strategy for reducing the incidence of parasitic diseases worldwide. *Reservoir hosts* are those that harbor parasites that cause disease in other hosts. For example, some mammals serve as reservoir hosts for *Trypanosoma cruzi*; while the intermediate host and vector for this parasite is primarily a family of triatomine bugs. Parasites that use a variety of reservoir hosts are more difficult to eradicate because they can utilize different hosts in their life cycle.

Classification of Parasitic Infection Types

Pathogenic parasites may be divided into three general categories based on their ability to cause clinical disease in humans (protozoa, helminths, and ectoparasites). Protozoa are unicellular microscopic eukaryotes that can survive and replicate within a human host. These parasites can be further classified based on transmission as either intestinal protozoa (eg, *Giardia, Cryptosporidium,* and *Entamoeba*) or blood and tissue protozoa (eg, *Plasmodium, Trypanosoma, and Babesia*). Helminths or worms are large complex multicellular organisms with life cycles that include an egg, larval, and adult stage. These parasites often complete the egg or larval stage outside the human host and ingestion of the organism at these stages leads to infection. Helminths can be further divided into either nematodes (roundworms) or platyhelminths (flatworms). Roundworm infection can occur in the gut (eg, adult stage of *Strongyloides*) or affect organs (eg, *Toxocara* larvae). Both cestodes (tapeworms such as *Taenia solium*) and trematodes (flukes) are considered flatworms, which are helminths that lack a central digestive body cavity. Medically important arthropods such as lice and mites are considered ectoparasites because these blood-feeding invertebrates can infest the skin and hair. Rather than causing infestations, some ectoparasitic arthropods such as the tick cause significant disease by acting as a vector for transmitting infectious pathogens to the human host. Overall, the extent of harm a parasite inflicts on a human host depends on factors such as parasite load, host nutritional status, and host immune status. As such, drug therapy selection depends not only on parasite characteristics but on these host factors also. This chapter discusses the major parasitic diseases including protozoan disease (giardiasis, cryptosporidiosis, amebiasis, Chagas disease, malaria, and babesiosis), helminthic infections (toxocariasis and cysticercosis), and ectoparasitic infestations (lice and scabies).

PROTOZOAN DISEASES

Giardiasis

Epidemiology and Etiology

Giardia lamblia (also known as *Giardia intestinalis* and *Giardia duodenalis*) is the most frequently identified parasitic cause of diarrhea in US patients. During 2012 to 2017, there were 111 giardiasis outbreaks, including 760 cases, reported to CDC from 26 states mostly affecting those in the northwestern and northeastern states.[7] It is most frequently reported in children between ages 1 and 4 years and peak illness occurs in late summer, possibly due to increased contact with contaminated water during the summer months or decreased immunity in children.[8,9]

Pathophysiology and Clinical Presentation

G. lamblia has two life-cycle stages: the cyst and the trophozoite. Human host infection starts with ingestion of *G. lamblia* cysts in fecally contaminated water or food. Following ingestion of as few as 10 cysts, which are moderately tolerant to chlorinated water and low gastric pH, each cyst releases two trophozoites. The pear-shaped trophozoite of *G. lamblia* has four pairs of flagella with two nuclei that lie in the area of the sucking disk, giving this protozoan a characteristic face-like image. The flagellated trophozoites colonize the mucosal tract and asexual replication of these trophozoites leads to localized edema, flattening of the villi, persistent diarrhea, and subsequent nutrient malabsorption.[10] Lactose intolerance precipitated by giardiasis and iron deficiency can persist after parasitic eradication. In addition, those infected may shed 10^8 to 10^9 cysts in their stool per day for weeks after initial infection, which further increases the risk for disease spread.

Primary risk factors for diarrhea due to *Giardia* include ingestion of contaminated untreated water, swimming, occupational exposure to infected human waste, and sexual activity that may involve fecal contact.[11]The primary modes of transmission in the United States are water exposure (26%), person-to-person contact (25%), and contaminated food (5%).[7] In countries where giardiasis is endemic, infection risk and diarrhea severity may increase among immunocompromised human immunodeficiency virus (HIV)–infected adults. A giardiasis diagnosis in a patient with diarrhea should only be suspected in patients with the aforementioned risk factors who also fit the epidemiologic profile of infected patients (Table e138-1). In the absence of these specific exposures, more prevalent alternative etiologies of community-acquired infectious diarrhea such as enteric viruses or *Clostridioides difficile* should be investigated before parasitic causes are considered.[12,13]

TABLE e138-1

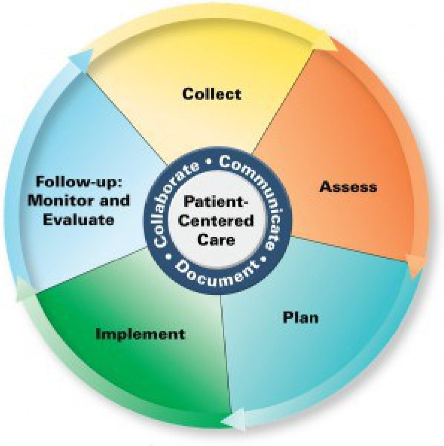
Clinical Presentation of Intestinal Protozoan Diseases

Giardiasis	Cryptosporidiosis	Amebiasis
Acute	Immunocompetent	Intestinal disease
Diarrhea: foul-smelling, copious, light-colored, fatty stools Cramp-like abdominal pain, bloating, and flatulence Malaise, anorexia, nausea, and belching	Diarrhea: profuse, watery, nonbloody Abdominal pain, fever, and vomiting Malaise, anorexia, joint pain, headache	Diarrhea: bloody (heme-positive in 100% of cases) with mucus Vague abdominal discomfort to severe abdominal cramps, flatulence Eosinophilia is usually absent, although moderate leukocytosis is not unusual
Chronic	Immunocompromised	Amebic liver abscess
Periods of diarrhea alternating with constipation Weight loss, lactose intolerance, vitamin B_{12}, and fat-soluble vitamin deficiencies	Diarrhea: cholera-like large amounts of watery diarrhea, weight loss, malabsorption Biliary, respiratory, or pancreatic dissemination	High fever, rigors, and profuse sweating, significant leukocytosis with left shift, and elevated alkaline phosphatase Right upper quadrant pain, hepatomegaly, and liver tenderness with referred pain to left or right shoulder

Data from References 12–15.

Giardia diagnosis may be made by enzyme immunoassays (EIA) or nucleic acid amplification testing (NAAT) of collected stool because these are 85% to 98% sensitive, 90% to 100% specific, rapid, reproducible, cost-effective, and do not require a trained microscopist.[12,14] Where these methods are unavailable, three stool specimens collected on separate days during the acute diarrheal phase for ova and parasites will yield up to 90% of the parasites if reviewed by an experienced microscopist.[14] Fresh stool specimens may show the trophozoites, whereas preserved specimens usually yield the cysts. Public health authorities should be notified once a giardiasis diagnosis is confirmed as this parasitic infection is designated as “Notifiable at the National Level” by the CDC.

Patient Care Process for Giardiasis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics: age, recent fluid intake, and description of diarrheal illness (eg, duration, stool appearance)
- Patient medical history: immunocompromising conditions
- Social history: alcohol use, recent travel, animal contact, and other high-risk activities (see Table e138-1)
- Current medications: recent antibiotics, nonprescription laxatives, antidiarrheal medications
- Objective data
  - Vital signs: temperature, blood pressure, heart rate, respiratory rate, height, weight
  - Physical exam: mucous membrane inspection, skin turgor, abdominal exam, appearance of stool
  - Labs: chemistry panel, urine output, hemoglobin, platelets
  - Diagnostic stool sample evaluation

Assess

- Dehydration (acute), malnutrition, and vitamin deficiencies (chronic)
- Alternative etiologies based on clinical presentation and risk factors (eg, *Clostridioides difficile, Cryptosporidium*)
- Medication adherence and preference for tablets versus liquid formulation
- Likelihood of outbreak based on probable source of *Giardia* infection (eg, swimming pool, well water)

Plan*

- Nonpharmacologic therapy including oral rehydration and hand hygiene
- Drug therapy regimen including fluid therapy, electrolyte replenishment, and specific anti-infective, dose, route, frequency, and duration (see Table e138-2)
- Monitoring parameters including efficacy (eg, diarrhea resolution, volume status, electrolyte balance, urine output, serum creatinine) and safety (eg, metallic taste, nausea)
- Patient education (eg, risk factor avoidance, hand hygiene, purpose of treatment, drug-specific information including antidiarrheal medication avoidance)
- Self-monitoring for resolution of diarrhea and rehydration

Implement

- Provide patient education regarding all elements of treatment plan
- Patient or caregiver to ensure additional sick contacts with diarrhea seek care
- Report confirmed giardiasis case to public health officials

Follow-up: Monitor and Evaluate

- Resolution of diarrhea within 4 to 7 days following completion of anti-infective regimen
- Presence of adverse effects (eg, metallic taste, nausea)

- Avoid recreational water venues for two or more weeks following symptom resolution

[*]Collaborate with patients, caregivers, and other healthcare professionals.

Treatment

1 Only patients with confirmed giardiasis should receive antiparasitic therapy. Since the primary clinical manifestation of giardiasis is prolonged diarrhea, clinicians must ensure patients receive adequate oral or intravenous fluids to maintain hydration, correct electrolyte abnormalities, and provide oral, enteral, or parenteral nutrition in severe cases. The antimotility agent loperamide and the antisecretory agent bismuth subsalicylate are available without a prescription, but should be avoided in children less than 18 years of age, immunocompromised patients, those with suspected toxic megacolon, or individuals with febrile diarrhea that may be due to a non-*Giardia* etiology.[12,13] The primary differences between recommended antiparasitic regimens for giardiasis are approved age for use, frequency of administration, duration of therapy, and commercially-available formulations (Table e138-2). Nitazoxanide and tinidazole are the only Food and Drug Administration (FDA)–approved medications for giardiasis. While the FDA has not approved metronidazole for this indication, it has been widely accepted as the mainstay of giardiasis therapy for the past 50 years.

TABLE e138-2

Treatment of Protozoan Diseases

	Adults	**Children**
Giardiasis[16,17]		
Tinidazole	2 g × single oral dose with food	≥3 years: 50 mg/kg orally × 1 dose with food (maximum 2 g)
Nitazoxanide	500 mg orally every 12 hours with food × 3 days	1-3 years: 100 mg orally every 12 hours with food × 3 days 4-11 years: 200 mg orally every 12 hours with food × 3 days ≥12 years: 500 mg orally every 12 hours with food × 3 days
Metronidazole	250 mg orally every 8 hours x 5 days	5 mg/kg orally every 8 hours x 5-7 days (maximum 250 mg dose)
Albendazole	400 mg orally once daily x 5 days	> 2 years: 10 mg/kg orally once daily x 5 days (maximum 400 mg dose)
Cryptosporidiosis[20,21]		
Nitazoxanide	Same as giardiasis dosing recommendations above for both adults and children	
Amebiasis[25–27]		
Asymptomatic Cyst Passer		
Paromomycin	8-12 mg/kg orally every 8 hours × 7 days	8-12 mg/kg orally every 8 hours × 7 days
Iodoquinol	650 mg orally every 8 hours × 20 days	10-13 mg/kg orally every 8 hours × 20 days (maximum 2 g/day)

Intestinal/Amebic Liver Abscess		
Metronidazole	750 mg orally or IV every 8 hours × 7-10 days	17 mg/kg orally or iv every 8 hours × 7-10 days (maximum 750 mg/dose)
Tinidazole	2 g daily × 3-5 days	≥3 years: 50 mg/kg daily × 3-5 days (maximum 2 g/dose)
	Each regimen for intestinal amebiasis/amebic liver abscess should be followed by a luminal agent	
Chagas disease[35–37]		
Benznidazole	2.5-4 mg/kg orally twice daily × 60 days (maximum 300 mg per dose)	2.5 - 4 mg/kg orally twice daily × 60 days (maximum 200 mg/dose)
Nifurtimox (CDC IND protocol only)	2-2.5 mg/kg orally every 6 hours × 90 days	≤10 years: 3.75-5 mg/kg orally every 6 hours × 90 days 11-16 years: 3.125-3.75 mg/kg orally every 6 hours × 90 days

Two clinical practice guidelines list nitazoxanide and tinidazole as a first-choice or preferred agent and metronidazole as an alternative regimen for giardiasis.[13,15] Efficacy at 1 to 4 weeks is 85% to 90% for tinidazole, 85% to 95% for metronidazole, 63% to 78% for nitazoxanide, and 69% to 86% for albendazole.[16] Albendazole has similar or lower efficacy than metronidazole.[16] Given the ease of use emerging evidence for greater efficacy, single-dose tinidazole is the preferred treatment for giardiasis. Metronidazole and tinidazole recipients most commonly report metallic taste and nausea as an adverse effect. Metronidazole has been used in the second and third trimesters of pregnancy. Paromomycin, an oral aminoglycoside, given at 25 to 35 mg/kg/day in three divided oral doses for 1 week is an alternative agent that can be given in all pregnancy trimesters because it is not systemically absorbed.

Evaluation of Therapeutic Outcomes

Patients should be assessed to achieve euvolemia if dehydrated and electrolyte balance should be restored. Diarrhea should stop within 3 to 6 days following treatment. While cyst excretion should also cease within days, patients should be advised to avoid recreational water venues for at least 2 weeks following resolution of diarrhea. During this time, patients should also follow strict hand hygiene and receive counseling on risk factor avoidance. Intestinal dysfunction (manifested as increased transit time) and radiologic changes (irregular thickening of the folds in the upper small intestine) may persist for months. Patients who fail initial therapy should preferably be treated with a drug from a different class.

Cryptosporidiosis

Epidemiology and Etiology

The protozoa genus *Cryptosporidium* is the leading cause of waterborne outbreaks of gastrointestinal illness in the United States and a major cause of mortality due to diarrhea in children under five, globally.[11,24,25] Between 2009 and 2017, there were 7,465 cases, 287 hospitalizations, and one death reported in the United States.[26] *C. hominis*, *C. parvum, and C. meleagridis* cause the majority of human cryptosporidiosis cases that lead to infectious diarrhea, but infection with many other *Cryptosporidium* species has been documented. Like giardiasis, the incidence rate of diarrheal illness due to *Cryptosporidium* is highest in children ages one through four and occurs primarily in the summer when increased exposure to recreational water occurs.

Pathophysiology and Clinical Presentation

The *Cryptosporodium* life cycle that occurs in the human host is more complex than *Giardia,* but transmission and infection principles remain similar.

Like giardiasis, host infection occurs when *Cryptosporidium* oocysts, which have an outer shell that allows them to be extremely tolerant to chlorinated water, are ingested from water or food that is contaminated with fecal matter. In the case of *Cryptosporidium,* the oocysts can remain viable >7 days in recreational pools.[11,26] After oral oocyst ingestion, nonflagellated sporozoites are released and infect the host's intestinal mucosa. Unlike *Giardia, Cryptosporodium* parasites undergo both sexual and asexual reproduction. Replicating parasites cause mucosal cell apoptosis, blunting of villi, diarrhea with chloride secretion, and impaired glucose and nutrient absorption.[10] Because the host immune response limits the severity of infection, symptomatic disease is mostly recognized in children or immunocompromised hosts. Watery diarrhea is the most common presentation and may be accompanied with abdominal cramps, nausea, vomiting, and fever. Prolonged infection causes malnutrition, inadequate nutrient absorption, and dehydration. Villous atrophy results in loss of enzymes such as lactase. Extraintestinal complications such as acalculous cholecystitis, sclerosing cholangitis, pancreatitis secondary to papillary stenosis, and pulmonary cryptosporidiosis may occur in immunocompromised patients.[27] The oocysts that develop following fertilization may sporulate in the host causing autoinfection or may be excreted in the stool allowing for transmission to other hosts following ingestion of less than 10 oocysts. Infected patients may shed infectious oocysts up to 2 weeks after diarrhea resolution.

The same risk factors for diarrhea due to *Giardia* should be present before suspecting cryptosporidiosis (Table e138-1). In addition to these risk factors, testing for *Cryptosporidium* infection is recommended in those with foodborne exposures including consumption of unpasteurized dairy products or contaminated fruits and vegetables and in immunocompromised patients such as those with acquired immunodeficiency syndrome. In patients with diarrhea lasting more than 1 to 2 weeks in whom common alternative etiologies have been excluded, a cryptosporidiosis diagnosis may be made by performing a *Cryptosporidium* direct fluorescent immunoassay, EIA, or NAAT on a collected stool sample. As several species of *Cryptosporidium* may cause human infection and each appear morphologically similar under microscopy, these methods are preferred for diagnosis because these point-of-care tests are rapid, widely available, and have high specificity and sensitivity of approximately 90%.[12-14] Cryptosporidiosis is also designated as "Notifiable at the National Level" by the CDC and should be reported to appropriate public health officials.

Treatment

Cryptosporidiosis treatment options are limited at present.[28] Correction of fluid and electrolyte abnormalities remains essential. Due to loss of villous glucose-stimulated sodium pumps, glutamine supplementation may enhance sodium absorption via glutamine-stimulated sodium pumps. Guidelines for treating cryptosporidiosis in HIV-infected adults recommend antimotility agents such as tincture of opium, which may be more effective than loperamide.[17] However, antimotility agents should be used with caution in young children.[15] Moreover, patients should avoid lactose-containing products such as milk.

② Only nitazoxanide is FDA-approved for cryptosporidiosis and its efficacy is suboptimal in HIV-infected patients. Although nitazoxanide dosing for cryptosporidiosis in non-HIV infected patients is the same as giardiasis treatment (Table e138-2), HIV guidelines recommend considering nitazoxanide 500 to 1,000 mg orally twice daily with food for 14 days in adults. For children living with HIV, the recommended dosing is the same as giardiasis with a recommended duration of treatment of 3 to 14 days. Nitazoxanide is effective in adults and children without HIV including a decrease in mortality in malnourished children.[13] However, only 33% of patients had diarrhea resolution compared to placebo. No improvement was observed in HIV-infected patients who received nitazoxanide who did not also receive effective antiretroviral therapy. As a result, it is imperative that HIV-infected patients with cryptosporidiosis receive antiretroviral therapy as the mainstay of therapy in addition to antiparasitic therapy.[13,15,17] Other drugs such as paromomycin, azithromycin, rifaximin, rifabutin, and protease inhibitors may have activity against *Cryptosporidium*, but lack robust clinical data. HIV guidelines recommend 14 to 21 days of paromomycin 500 mg orally four times a day as an alternative to nitazoxanide in adults only.

Evaluation of Therapeutic Outcomes

Rehydration, correction of electrolyte abnormalities, restoration of nutritional deficiencies, and resolution of diarrhea are key therapeutic outcomes. To avoid further transmission to others, it is important for patients to avoid recreational waters for at least 2 weeks after symptom resolution.[29] Antiparasitic therapy alone is not curative in immunosuppressed patients. As such, HIV-infected patients should be started on antiretrovirals and CD4+ T-cell counts may be followed. All patients, especially those with HIV and CD4+ T-cell counts less than 200 cells/μL (200×10^6/L), should be counseled on risk reduction by avoiding direct contact with stool from pets, maintaining good hand hygiene, refraining from drinking untreated water, and staying away from swimming in freshwater or public recreational water facilities. When traveling to developing countries, using tap water to brush teeth or to wash raw fruits or vegetables should be avoided. Boiling water for at least 1 minute or using bottled water is recommended.

Amebiasis

Epidemiology and Etiology

Amebiasis is caused by the enteric protozoan pathogen *Entamoeba histolytica*. Morphologically, there are three species of Entamoeba that are indistinguishable from *E. histolytica: E.dispar, E. moshkovskii,* and *E. Bangladeshi. E. dispar* and *E. bangladeshi* are associated with an asymptomatic carrier state and do not typically cause disease in the human host.[30] *E. moshkovskii*, however, has been associated with noninvasive diarrhea in children and experimentally induced colitis in mice. Amebiasis caused an estimated 15,400 deaths and represented approximately 3% of all deaths due to diarrheal illness in 2015.[24,31-33] In Asia and Africa, amebiasis was among the top seven pathogens causing dysentery among children <5 years of age.[34] In the United States, amebiasis accounts for approximately 1.4 million hospitalizations and five deaths per year and most commonly affects young Hispanic men living in southwestern states along the Mexican border.[31-33] In the United States, *E. histolytica* is classified as a biodefense research category B because of its low infective dose, resistance to chlorine and environmental stability.[35] These characteristics have also resulted in outbreaks from consumption of contaminated municipal water.[35]

Pathophysiology and Clinical Presentation

As was described with other enteric protozoa, oral ingestion of mature *E. histolytica* cysts from fecal material initiates the parasitic host invasion cycle. Excystation occurs in the small intestine and released trophozoites migrate to the colon. *E. histolytica* trophozoites reproduce in the same manner as *G. lamblia.* In 90% of cases trophozoites convert to cysts, which are shed in the host's stool. This results in asymptomatic disease, but allows the human host to serve as an important reservoir for *E. histolytica* transmission. In 10% to 20% of cases, *E. histolytica* trophozoites will invade mucosal cells of colonic epithelium and produce necrotizing ulcers in the submucosa, which leads to abdominal pain with bloody, mucoid diarrhea.[10] Invasion into the bowel wall gives access to the portal circulation and enables hematogenous spread to the liver where they may form abscesses and periportal fibrosis. Extrahepatic extension to the chest is the second most common extra-abdominal manifestation of disease and typically involves direct extension of a hepatic abscess into the thoracic space. Pericardial disease can occur from rupture of a left hepatic lobe abscess or from extension from a pleural abscess.[37] Hematogenous spread to the brain occurs in up to 4.7% of patients with amebic liver abscesses (ALAs).[38]

③ *E. histolytica* is endemic in resource-limited countries and at-risk individuals include immigrants, persons with recent travel to endemic countries, men who have sex with men, and individuals with and history of oral-anal contact.[13,33] Clinicians should suspect amebiasis in patients with these risk factors who develop dysentery, colitis, or intestinal perforation with or without liver abscesses (Table e138-1). Stool sample analysis is insensitive and does not distinguish between *E. histolytica* and the nonpathogenic Entamoeba. As a result, *E. histolytica*-specific antigens and real-time polymerase chain reaction (PCR) tests are the preferred diagnostic platforms to diagnose acute amebiasis.[13,14] The FDA has approved a stool antigen detection test with a sensitivity and specificity of 98% and 100%, respectively, while other available stool EIAs have sensitivities and specificities that range from 93% to 100% for diagnosis of intestinal disease.[14,39] PCR testing, considered the gold standard for diagnosis, has the best sensitivity and is available through various FDA-cleared gastrointestinal panels.[40] It has excellent sensitivity in the evaluation of ALA, identifying *E. hystolitica* in 20 of 23 hepatic samples obtained from patients with ALA.[41] Additionally, serum-based EIAs and antibody detection tests have sensitivities greater than 92% and specificities that range from 80% to 100% for extraintestinal disease. Endoscopy with biopsy may provide more definitive diagnosis and help evaluate for other infectious and non-infectious etiologies of colitis such as tuberculosis and inflammatory bowel disease when stool diagnostic testing has been inconclusive. When ALA is suspected from initial physical examination and history, various imaging modalities are available to aid in diagnosis, such as liver ultrasound, abdominal computed tomography (CT), and magnetic resonance imaging (MRI). Leukocytosis and an elevated alkaline phosphatase concentration are common findings in patie. In rare instances, needle aspiration of the hepatic abscess may be attempted using ultrasound guidance to assist with diagnosis.[14]

Treatment

Recommended treatment regimens depend on the category of amebiasis: asymptomatic cyst passers, intestinal amebiasis, and ALA (Table e138-2). Rehydration with clean water, electrolyte replacement, and nutritional support are essential adjunctive treatment modalities. Percutaneous drainage may be required for management of hepatic abscesses greater than 5 to 10 cm, abscesses involving the left hepatic lobe or pericardium and if there is no clinical response to drug therapy within 5 to 7 days. Most regimens require a combination of drugs administered concurrently or sequentially.

④ Metronidazole and tinidazole are tissue-acting agents, whereas paromomycin and iodoquinol are luminal amebicides. A systemic agent may be so well absorbed that only small amounts of the drug stay in the bowel, which might prove ineffective as a luminal agent. A luminal-acting agent, on the other hand, may be too poorly absorbed to be effective in the tissue. In the asymptomatic cyst passer, it is necessary to eradicate the causative agent from the lumen to prevent intestinal amebiasis or the development of ALA.

Asymptomatic cyst passers and patients with mild intestinal amebiasis should receive one of the following luminal agents: paromomycin or iodoquinol.[18,19] Paromomycin is the preferred luminal agent in pregnant patients. Patients with severe intestinal disease or liver abscess should receive metronidazole or tinidazole followed by a course of one of the luminal agents.[20]

Evaluation of Therapeutic Outcomes

Most patients with either intestinal amebiasis or colitis will respond in 3 to 5 days with amelioration of symptoms. Patients with liver abscesses may take up to 7 to 10 days to respond. Patients not responding during this period may require aspiration of abscesses or exploratory laparotomy. Serial liver scans have demonstrated healing of liver abscesses over 4 to 8 months after adequate therapy.

Travelers and tourists visiting an epidemic area should avoid local tap water, ice, salads, and unpeeled fruits. Travel kits for water decontamination are available for purchase, but boiled water is safest. An alternative or additional measure may be to carry a portable water purifier. Because food handlers may be a source of amebiasis, travelers should avoid eating at food stalls and open markets.

Chagas Disease (American Trypanosomiasis)

Epidemiology and Etiology

Trypanosoma brucei gambiense, *T. brucei*, and *T. brucei rhodesiense* are tissue protozoan parasites that cause African trypanosomiasis (sleeping sickness) and *T. cruzi* is the agent that causes American trypanosomiasis (Chagas disease). Further discussion of this subject will focus on American trypanosomiasis. Chagas disease is considered a neglected parasitic infection by the CDC. Over 180,000 new cases of Chagas disease occurred globally with over 7,000 deaths in 2016.[1,3] Six to 10 million people are affected globally and about 300,000 infected patients reside in the United States.[42-44] The majority of *T. cruzi* infections occur in Latin America where over 5.7 million patients were infected in 2010 with over 15% from Mexico and 42% from Brazil and Argentina.[45,46] Immigrants from El Salvador and Mexico are at highest risk for Chagas disease in the United States and the most prevalent number of cases occur in California (greater than 70,000), Texas (almost 37,000), Florida (greater than 18,000), and New York (almost 17,500).[42,44,47]

Pathophysiology and Clinical Presentation

The two major life cycle forms of *T. cruzi* include the nondividing motile flagellated trypomastigote and the nonmotile intracellular amastigote, which undergoes asexual binary fission.[48] *T. cruzi* is considered a blood or tissue protozoan and is transmitted to the human host by the reduviid bug or kissing bug species (*Triatoma*, *Rhodnius, and Panstrongylus*) that live in wall cracks of houses in rural areas of North, Central, and South America, and less commonly via transfusion, organ transplant, contaminated food or drink, and vertical transmission.[17,48] The reduviid bug vector becomes infected after sucking blood from animals (eg, opossums, dogs, and cats) or humans infected with circulating trypomastigotes at night.[48] The infected vector takes a blood meal from a human host and releases fecal trypomastigotes, which enter the host near the bite wound. The bite may cause intense itching and may result in a chagoma, which is a painful erythematous subcutaneous nodule that forms at the bite site.[10,48] If trypomastigotes enter the host through ocular mucosa, a unilateral conjunctivitis known as Romaña's sign appears. Once inside the host, trypomastigotes transform into intracellular amastigotes. Intracellular amastigotes replicate and transform back into trypomastigotes, which then enter the bloodstream following cell rupture and cause infection in other host tissues. The incubation period is 1 to 2 weeks. Acute phase of the infection generally presents with mild and nonspecific (eg, fever, malaise, hepatosplenomegaly) symptoms and rarely (<1%) patients develop severe and life-threatening symptoms as a result of meningoencephalitis or myocariditis.[49] After 8 to 10 weeks of persistent *T. cruzi* parasitemia, untreated patients develop chronic complications of Chagas disease and serve as a reservoir host that transmits *T. cruzi* to reduviid bugs that bite the infected host.

In chronic trypanosomiasis, 20% to 30% of patients present with cardiomyopathy and heart failure (see Table e138-1).[48] Electrocardiograms (ECGs) are usually abnormal, demonstrating extrasystoles, first-degree heart block, right bundle-branch block, and other serious conduction disturbances.[44,50]

Degeneration of the autonomic ganglia in the smooth muscle of the esophagus and colon leads to uncoordinated peristalsis. The end result of chronic *T. cruzi* parasitemia and tissue invasion is "megasyndromes" of affected organs.[48,50] Penetration of the central nervous system (CNS) results in meningoencephalitis, strokes, seizures, and focal paralysis. In HIV coinfected patients, meningoencephalitis is the most common manifestation.[17]

T. cruzi exposure history is essential in risk-stratifying patients during initial diagnostic workup and clinicians should aim to diagnose Chagas disease early before cardiac complications occur. At least two positive serologic tests using the indirect hemagglutination assay (IHA), immunofluorescent antibody test (IFA), or enzyme-linked immunosorbent assay (ELISA) is diagnostic for the disease. A PCR test has also been most useful in monitoring for early treatment failure as opposed to an initial diagnosis.[48] Once a diagnosis is made, baseline ECG, chest X-ray, and echocardiograph are recommended along with serial evaluation based on clinical findings.[44]

Treatment

⑤ Benznidazole is the only FDA-approved treatment for Chagas disease. While a 60-day benznidazole course is only indicated in children from 2 to 12 years of age, all patients with acute, early chronic, and reactivated Chagas disease should receive treatment except patients with established cardiomyopathy.[44] For adults weighing >60 kg, a longer duration of treatment may be needed and optimal duration of therapy is unknown for HIV coinfected patients.[17,44] Antitrypanosomal therapy is generally not recommended for pregnant patients due to concerns for toxicity and limited experience.[48] While treatment results in serologic or PCR conversion, the incidence of progressive cardiac complications remains unchanged.[21,22] Side effects of benznidazole include neuropathy, rash, and granulocytopenia, which may lead to discontinuation in up to 30% of patients. Approximately 30% to 50% of benznidazole-recipients experience allergic dermatitis, which can be managed with antihistamines, corticosteroids, or both.[48] Nifurtimox, the only alternative *T. cruzi* infection treatment option, is only available under a CDC investigational protocol and should be reserved for benznidazole treatment failures. Also, up to 75% of nifurtimox recipients discontinue therapy due to adverse effects, which include gastrointestinal disturbances (anorexia, nausea, vomiting), CNS toxicity (headache, vertigo, insomnia), myalgias, and peripheral neuropathy.[23] Lastly, allopurinol monotherapy and triazoles such as posaconazole as monotherapy or in combination with antitrypanosomal agents were ineffective for treatment of Chagas disease and should be avoided.[51,52]

Evaluation of Therapeutic Outcomes

Unfortunately, reliable tests of cure are currently unavailable because serologic markers used to diagnose Chagas disease may remain positive for years after completion of therapy. Instead, early visits evaluating for clinical progression is recommended followed by annual serologic testing. Quantitative PCR results may become a useful way to monitor for early treatment failure, but is an unreliable surrogate marker for visceral complications.[22] Patients should receive at least annual 12-lead ECG evaluations regardless of the extent of cardiac involvement on presentation.[44,48] Primary preventative measures involve vector control and there is no vaccine available.[53]

Malaria

Epidemiology and Etiology

Malaria is the most devastating disease in terms of human suffering and economics. In 2019, there were 229 million cases and 409,000 deaths reported by the World Health Organization (WHO). Although this is a decline from 720,000 deaths reported in 2016, this remains the third leading cause of death in children under the age of 5 accounting for 274,00 malaria deaths in 2019.[54] Fortunately, malaria incidence and the death rates have declined in recent years, yet still nearly half the world's population remains at risk for malaria.[1,2,54] In the United States, over 99% of malaria cases are imported and malaria remains the most common cause of hospitalization due to travel-associated disease.[55] In 2017, 2,161 cases of malaria were reported to the CDC, representing the highest number of cases in the United States since 1971 and 86% of the cases were from Africa. Overall, 70.5% of all cases were due to *Plasmodium falciparum*, 14.4% of cases were classified as severe, and seven patients died.[56] Despite chemoprophylaxis and mosquito avoidance measures recommended to those who travel to endemic regions, in 2017 only 28.4% of the cases with chemoprophylaxis data, reported taking chemoprophylaxis.[56]

The four predominant *Plasmodia* species that cause malaria include *P. falciparum, P. vivax, P. malariae,* and *P. ovale*. *P. knowlesi* is now recognized as a fifth human pathogen causing significant disease in Malaysia.[57] These blood and tissue protozoa are transmitted by the bite of an infected *Anopheles* mosquito—the malaria vector. *P. vivax* is more prevalent in India, Pakistan, Bangladesh, Sri Lanka, and Central America, whereas *P. falciparum* is predominant in Africa, Haiti, Dominican Republic, the Amazon region of South America, and New Guinea.[58] Most of the infections with *P. ovale* are mixed infections and occur predominantly in Africa and also in parts of Asia and Oceania.[66] The distribution of *P. malariae* is worldwide.[40] Determining species' geographic distribution is important for choosing chemoprophylaxis and empiric treatment regimens.

Pathophysiology and Clinical Presentation

Plasmodium sporozoites (tissue protozoa) enter the host bloodstream following the bite of an infected female *Anopheles* mosquito. The sporozoites invade parenchymal hepatocytes, multiply in stages referred to as *exoerythrocytic stages*, and become hepatic vegetative forms or schizonts. Schizonts rupture to release thousands of daughter cells, or merozoites (blood protozoa), that then infect erythrocytes.[10] Merozoites within erythrocytes undergo asexual reproduction, develop into ring forms, trophozoites, schizonts, and finally, merozoites, which then invade other erythrocytes. The erythrocytic phase causes extensive hemolysis, which results in anemia and splenomegaly.

Clinical presentation of malaria differs based on the infecting species (Table e138-3). *P. vivax* and *P. ovale* can exist in the liver in the latent exoerythrocytic form (hypnozoites) for extended periods and, therefore, infected subjects can experience relapses. *P. falciparum* and *P. malariae* remain in the exoerythrocytic stage in the liver for about 4 weeks before invading erythrocytes.[58,59] *P. malariae* is implicated in immune-mediated glomerulonephritis and nephrotic syndrome. *P. falciparum* infection causes serious complications for several reasons. This species can invade erythrocytes of all ages causing high levels of parasitemia and the parasites can sequester in capillaries and postcapillary vessels of organs such as the brain and the kidney.[58,59] Tissue hypoxia from anemia, together with *P. falciparum*-parasitized red blood cell adherence to endothelial cells in capillaries, likely contribute to extensive vascular disease and severe metabolic effects. Children younger than 5 years old and pregnant women are at high risk for severe complications from falciparum malaria.[60] *P. knowlesi* appears identical to *P. malariae* on blood smear, but clinically causes more severe disease. *P. knowlesi* replicates every 24 hours causing daily fever spikes and hyperparasitemia. Severe cases have been associated with metabolic acidosis, hepatorenal dysfunction, respiratory distress, severe anemia, and refractory hypotension.[57]

TABLE e138-3

Clinical Presentation of Malaria

Initial presentation Nonspecific fever, chills, rigors, diaphoresis, malaise, vomiting, orthostatic hypotension, electrolyte abnormalities
Erythrocytic phase Prodrome: headache, anorexia, malaise, fatigue, and myalgia Nonspecific complaints such as abdominal pain, diarrhea, chest pain, and arthralgia Paroxysm: high fever, chills, and rigor Cold phase: severe pallor and cyanosis of the lips Hot phase: fever between 40.5°C (104.9°F) and 41°C (105.8°F) Sweating phase: Follows hot phase by 2-6 hours where fever resolves Marked fatigue and drowsiness, warm, dry skin, tachycardia, cough, severe headache, nausea, vomiting, abdominal pain, diarrhea, and delirium Lactic acidosis and hypoglycemia (with falciparum malaria) Anemia and splenomegaly
P. falciparum infections Hypoglycemia, acute renal failure, pulmonary edema, severe anemia, thrombocytopenia, high-output heart failure, cerebral congestion, seizures and coma, and adult respiratory syndrome

Data from References 49,58.

Effective malaria management is predicated on rapid diagnosis. Point-of-care rapid antigen detection tests that require finger-prick blood are widely available. These tests detect *P. falciparum* histidine-rich protein 2, *Plasmodium*-specific lactate dehydrogenase, or aldolase antigens, but generally require confirmatory testing because they may lack adequate sensitivity in detecting non-*falciparum* infections or those with low-level parasitemia.[61,62] The FDA has approved the ID-Fluorescent in situ hybridization Plasmodium Genus Test Kit, a qualitative test for detection of malaria parasites in blood smears that has an overall sensitivity of 95% for detection of *P. falciparum* and 90% sensitivity for identification of *P. vivax*.[63] NAATs are also available at various CLIA accredited laboratories, but may be expensive, unavailable, and follow-up microscopy is recommended to quantify parasitemia.[61] As such, microscopy remains the gold standard for malaria diagnosis. To ensure a positive diagnosis, thick and thin blood smears should be obtained every 12 to 24 hours for three consecutive days. Confirmed malaria cases should be reported to appropriate public health authorities.

Chemoprophylaxis and Prevention

⑥ Along with nonpharmacologic measures to avoid mosquito bites (diethyltoluamide- or picaridin-containing repellant use, full-coverage clothing, window screens, insecticide-impregnated nets, and air-conditioned rooms), chemoprophylaxis is recommended for all those travelling to areas where malaria exposure is possible. Specific antimalarial recommendations vary depending on local susceptibility patterns and can be found in the CDC Yellow Book or on the CDC Website. Of note, approximately 95% of US residents who traveled to an endemic region and were reported to have developed malaria upon return did not adhere to or did not take a CDC-recommended chemoprophylaxis regimen.[64] Clinicians have increasingly prescribed non-chloroquine antimalarial drugs such as atovaquone-proguanil and doxycycline for chemoprophylaxis because these regimens retain effectiveness in areas where chloroquine-resistant *P. falciparum* exposure is likely (Table e138-4). Antimalarial drugs that lack activity against the liver stage or preerythrocytic stage of infection must be given during and at least 4 weeks after leaving an endemic area.

TABLE e138-4

Chemoprophylaxis of Malaria

	Adults	Children	Notes
Chloroquine-susceptible area			
Chloroquine	300 mg base orally once weekly	5 mg/kg base orally once weekly (max 300 mg/dose)	Begin 1-2 weeks before travel. Continue 4 weeks after leaving.
Hydroxychloroquine	310 mg base orally once weekly	5 mg/kg base orally once weekly (max 310 mg/dose)	
Mefloquine	228 mg base orally once weekly	≤9 kg: 4.6 mg/kg base orally once weekly 9-19 kg: ¼ tablet orally once weekly 19-30 kg: ½ tablet orally once weekly 30-45 kg: ¾ tablet orally once weekly >45 kg: 1 tablet orally once weekly	Begin ≥2 weeks before travel. Continue 4 weeks after leaving. Contraindicated in those with psychiatric disorders. Caution in those with cardiac conduction abnormalities.
Chloroquine-resistant area			
Atovaquone-progaunil Adult tablet: 250 mg/100 mg Pedi tablet: 62.5 mg/25 mg	1-adult tablet orally daily	5-8 kg: ½ pediatric tablet orally daily 8-10 kg: ¾ pediatric tablet orally daily 10-20 kg: 1-pediatric tablet orally daily 20-30 kg: 2-pediatric tablets orally daily	Begin 1-2 days before travel. Continue 7 days after leaving. Contraindicated in those with a CrCl <30 mL/min (0.5 mL/s).

		30-40 kg: 3-pediatric tablets orally daily >40 kg: 1-adult tablet orally daily	
Doxycycline	100 mg orally daily	≥8 years: 2.2 mg/kg orally daily (max 100 mg/dose)	Begin 1-2 days before travel. Continue 4 weeks after leaving. Contraindicated in pregnancy.
P. vivax endemic areas			
Primaquine	30 mg base orally once daily	0.5 mg/kg base orally daily (max 30 mg/dose)	Begin 1-2 days before travel. Continue 7 days after leaving. Contraindicated in G6PD deficiency and pregnancy.
Tafenoquine	200 mg (2 tablets) orally daily × 3 days before travel 200 mg (2 tablets) orally weekly during travel 200 mg (2 tablets) orally once 1 week after travel	Only indicated for patients ≥18 years	May be used as prophylaxis against all *Plasmodium* species including those found in chloroquine-susceptible and chloroquine-resistant areas. Contraindicated in G6PD deficiency and pregnancy.

Data from References 40,41,45.

Treatment

A rapid malaria diagnosis, especially of *P. falciparum*, is essential because antimalarial therapy given within 48 to 72 hours can decrease risks of high-mortality complications such as hypoglycemia, pulmonary edema, and renal failure. Malaria treatment has changed in recent years with the availability of artemisinin-based antimalarials (Fig. e138-1). Artesunate and artemether-lumefantrine are approved for use in the United States. Artesunate for Injection™ has been approved by the FDA and is now commercially available, however, until it is fully distributed across United States, the CDC will continue to distribute artesunate under its investigational new drug (IND) protocol when artesunate is not available within 24 hours of a clinician requesting the drug. The CDC will monitor the availability of Artesunate for Injection™ and will provide updates prior to stopping the IND program.[65,66] Other artemisinin-based antimalarial drugs found worldwide include dihydroartemisinin-piperaquine, artesunate-amodiaquine, and artesunate-pyronaridine.[58,59]

Severe malaria is defined as those patients with a confirmed malaria diagnosis who also have one of the following: impaired consciousness, severe normocytic anemia (hemoglobin less than 7 g/dL [70 g/L; 4.34 mmol/L]), acute kidney injury, pulmonary edema or acute respiratory distress syndrome, septic shock, disseminated intravascular coagulation or spontaneous bleeding, acidosis, jaundice, seizures, or parasitemia of more than 5%.[67] In the past, those patients with severe illness including *P. falciparum* have received parenteral quinidine as the drug of choice, but evidence from randomized controlled trials support the superiority of artesunate over quinidine.[68] Furthermore, intravenous quinidine has been discontinued and is no longer available in the United States. As such, artesunate is the drug of choice for the treatment of severe malaria. While waiting for artesunate delivery, if not locally available, clinicians may opt to give a single dose of artemether-lumafantrine, atovaquone-proguanil, or quinine via a nasogastric tube.

In uncomplicated malaria, options include artemether-lumefantrine, atovaquone-progaunil, quinine plus doxycycline, quinine plus clindamycin, chloroquine, or hydroxychloroquine depending on the infecting species and likelihood of chloroquine resistance. Patients with *P. vivax* and *P. ovale* infections should also be given an 8-aminoquinoline such as tafenoquine or primaquine to eradicate dormant hypnozoites found in the liver (radical cure). Dosing regimens can be found in Table e138-5.

TABLE e138-5

Recommended Doses for Malaria Treatment

	Adults	Children	Notes
Severe malaria			
Artesunate	2.4 mg/kg IV × 1, then at 12, 24, and 48 hours (may continue once daily if necessary)		Artesunate is available as Artensunate for Injection^{TM} but if it cannot be obtained within 24 hours, it is available under CDC IND protocol at 770-488-7788 or 770-488-7100
Uncomplicated *P. falciparum* or chloroquine-resistant			
Artemether-lumafantrine Tablet: 20 mg/120 mg	4 tablets orally twice daily × 3 days	5-15 kg: 1 tablet orally twice daily × 3 days 15-25 kg: 2 tablets orally twice daily × 3 days 25-35 kg: 3 tablets orally twice daily × 3 days ≥35 kg: 4 tablets orally twice daily × 3 days	Second dose should be taken 8 hours after initial dose. Take with food or milk. Equal recommendation given in 2013 malaria guidelines to atovaquone- and quinine-based regimens.
Atovaquone-proguanil Adult tablet: 250 mg/100 mg Pedi tablet: 62.5 mg/25 mg	4 adult tabs orally daily × 3 days	5-8 kg: 2-pediatric tablets orally daily × 3 days 8-10 kg: 3-pediatric tablets orally daily × 3 days 10-20 kg: 1-adult tablet orally daily × 3 days 20-30 kg: 2-adult tablets orally daily × 3 days 30-40 kg: 3-adult tablets orally daily × 3 days >40 kg: 4-adult tablets orally daily × 3 days	Take with food or milk. Equal recommendation given in 2013 malaria guidelines to artemisinin- and quinine-based regimens.
Quinine sulfate plus: either doxycycline or clindamycin	542 mg base orally three times daily × 3-7 days 100 mg orally	8.3 mg/kg base orally three times daily × 3-7 days ≥8 years: 2.2 mg/kg	Equal recommendation given in 2013 malaria guidelines to artemisinin- and atovaquone-based regimens.

	twice daily × 7 days 6.7 mg/kg/orally three times × 7 days	orally twice daily × 7 days 6.7 mg/kg/orally three times daily × 7 days	
Mefloquine	648 mg base orally × 1, then 456 mg base orally 6-12 hours later	13.7 mg/kg base orally × 1, then 9.1 mg/kg base orally given 6-12 hours later	High rate of severe neuropsychiatric reactions.
Uncomplicated chloroquine-susceptible malaria			
Chloroquine	600 mg base orally × 1, then 300 mg base orally at 6, 24, 48 hours	10 mg/kg base orally × 1, then 5 mg/kg base orally at 6, 24, 48 hours	May also use the above-mentioned regimens.
Hydroxychloroquine	620 mg base orally × 1, then 310 mg base orally at 6, 24, 48 hours	10 mg/kg base orally × 1, then 5 mg/kg base orally at 6, 24, 48 hours	May also use the above-mentioned regimens.
P. vivax or *P. ovale* malaria			
Tafenoquine	300 mg (2 tablets) × 1 dose	Only indicated in patients ≥16 years	Add to above regimens to eradicate dormant liver hypnozoites; contraindicated in G6PD deficiency; FDA-approved for radical cure of *P. vivax* (not *P. ovale*)
Primaquine	30 mg base orally daily × 14 days	0.5 mg/kg base orally daily × 14 days	Add to the above regimens to eradicate dormant liver hypnozoites; contraindicated in G6PD deficiency.

Data from References 40,41,47.

Evaluation of Therapeutic Outcomes

The CDC recommends checking blood smears every 12 to 24 hours to assess for an appropriate response to therapy. For severe infection, blood smears should be studied until clearance of parasitemia is documented. Hypoglycemia that is associated with *P. falciparum* should be checked and corrected with dextrose infusions. Once the parasite count is <1% and the patient can tolerate oral therapy, the patient should receive a full-treatment course with one of the recommended regimens (artemether-lumefantrine, atovaquone-proguanil or quinine plus doxycycline or clindamycin).[58,59] Patients treated with IV artesunate for severe malaria should be monitored weekly for up to 4 weeks for evidence of hemolytic anemia by checking weekly hemoglobin, reticulocyte count, lactate dehydrogenase, and total bilirubin. Cases of delayed-post artemisinin hemolytic anemia should be reported.[67] Increasing incidence of artemisinin-resistant and chloroquine-resistant malaria found in Western Cambodia, Thailand, and Myanmar present a great threat to malaria control. Malaria does not produce immunity in patients. While research is being conducted to develop a malaria vaccine, a licensed vaccine remains unavailable.

Babesia

Babesiosis is caused by the species, Babesia, an intraerythrocytic protozoa transmitted by hard-bodied ticks. There are several species that infect humans throughout the world, including *Babesia microti, Babesia duncani*, and *Babesia divergens* in the United States.[69] There are over 2,000 cases of babesiosis reported to the CDC annually mostly attributed to the species, *B. microti*. Infection typically occurs not only from the bite of a *B. microti*–infected Ixodes scapularis tick, but can also be transmitted through blood transfusion, organ transplantation, and perinatally. *B. microti* has become a leading pathogen in transfusion-associated infections in the United States, responsible for death in 20% of blood recipients infected with babesia. This has led to recommendations to screen the blood supply for *Babesia spp.* in babesiosis endemic states.

Cases typically present with fever, fatigue, chills, night sweats, and anorexia. Severe babesiosis may cause severe anemia, acute respiratory distress syndrome, disseminated intravascular coagulation, liver failure, heart failure, and shock and requires close monitoring and hospitalization. About half of the babesiosis cases reported to the CDC between 2011 and 2015, for which clinical data was available, resulted in hospitalization and nearly one-third had one or more complications.[70] While the diagnosis is clinical and based on epidemiological risk factors, confirmation of acute babesiosis is based on peripheral blood smear examination or PCR.[69] Thick and thin blood smears should be prepared and examined by experienced personnel. Although the number of microscopic fields has not been standardized, evaluation of over 200 hundred oil immersion fields will increase sensitivity. Trophozoites may resemble malaria, but identification of merozoites organized in tetrads, the Maltese cross forms, are pathognomonic for babesiosis. Microscopy provides fast results, but PCR can be useful when laboratory personnel are inexperienced or there is low level of parasitemia. Antibody testing is available, but not recommended for diagnosis of acute babesiosis.[74]

Treatment

Asymptomatic carriers of *Babesia spp*. do not require treatment as they typically clear the infection within 1 year, unless parasites are seen on thin blood smear for more than a month. The preferred treatment regimen for babesiosis is the combination of atovaquone and azithromycin for 7 to 10 days, often extended in immunocompromised patients (at least 6 weeks for highly immunocompromised patients).[69] Mild to moderate disease can be treated with oral regimens whereas hospitalized patients with severe disease will require IV regimens initially and can be transitioned to oral therapy (Table e138-6). The combination of clindamycin and quinine is an alternative treatment due to poor tolerability of quinine leading to low adherence. Patients with high-grade parasitemia (>10%) or who have severe manifestations may be considered for exchange transfusion. Consultation with infectious diseases and transfusion specialists is recommended. Daily monitoring parameters include hematocrit, platelet count, liver enzymes, renal function and parasitemia levels until symptoms abate and parasitemia is reduced to <4%. Symptoms typically improve within 2 days of initiation of therapy and resolve within 1 to 2 weeks. However, fatigue and low-grade parasitemia may persist for a few months, but do not imply treatment failure (see Table e138-6).

TABLE e138-6

Treatment of Babesiosis

Patient Category	Adult	Children
Mild-to-moderate babesiosis	Preferred: Atovaquone 750 mg orally twice daily with food plus azithromycin 500 mg orally on day 1, then 250 mg once daily for 7-10 days Alternative: Clindamycin 600 mg orally every 8 hours plus quinine sulfate 542 mg base orally every 6-8 hours for 7-10 days	Preferred: Atovaquone 20 mg/kg (maximum 750 mg) orally twice daily plus azithromycin 10 mg/kg (maximum 500 mg) orally on day 1, then 5 mg/kg (maximum 250 mg) once daily for 7-10 days Alternative: Clindamycin 7-10 mg/kg (maximum 600 mg) orally every 8 hours plus quinine sulfate 6 mg base/kg (maximum 542 mg base) orally every 6-8 hours for 7-10 days
Severe babesiosis (hospitalized)	Preferred: Atovaquone 750 mg orally twice daily plus azithromycin 500-1,000 mg intravenously once daily until symptoms abate, then convert to oral step-down therapy Alternative: Clindamycin 600 mg intravenously every 6 hours plus quinine sulfate 542 mg base orally every 6-8 hours until symptoms abate, then convert to oral step-down therapy	Preferred: Atovaquone 20 mg/kg (maximum 750 mg) orally twice daily plus azithromycin 10 mg/kg (maximum 500 mg) intravenously once daily until symptoms abate, then convert to oral step-down therapy Alternative: Clindamycin 7-10 mg/kg (maximum 600 mg) intravenously plus quinine sulfate 6 mg base/kg (maximum 542 mg base) orally every 6-8 hours until symptoms abate, then convert to oral step-down therapy
Step-down therapy for hospitalized patients	Preferred: Atovaquone 750 mg orally twice daily plus azithromycin 250-500 mg orally once daily to complete a total of 7-10 days; azithromycin 500-1000 mg should be considered for immunocompromised patients Alternative: Clindamycin 600 mg orally every 8 hours plus quinine sulfate 542 mg base orally every 6-8 hours to complete a total of 7-10 days	Preferred: Atovaquone 20 mg/kg (maximum 750 mg) orally twice daily plus azithromycin 10 mg/kg (maximum 500 mg) orally once daily to complete a total of 7-10 days Alternative: Clindamycin 7-10 mg/kg (maximum 600 mg) orally every 8 hours plus quinine sulfate 6 mg base/kg (maximum 542 mg base) orally every 6-8 hours to complete a total of 7-10 days

HELMINTHIC DISEASES

Endemic helminthic infections are uncommon in the United States, but the infection prevalence may be as high as 1.5 billion in Asia, Latin America, the Caribbean, and Sub-Saharan Africa.[1] In the United States, helminth infections are most often imported, but may be acquired locally from exposure to domestic or wild animals, improperly prepared food, or as a consequence of poverty and poor sanitation.[71] Most intestinal helminthic infections may not be associated with clearly defined manifestation of disease, but they can cause significant pathology. One factor that determines the pathogenicity of helminths is their population density. Light infections may be fairly well tolerated, whereas high populations of intestinal helminths can result in predictable disease presentations. Certain conditions and drugs (fever, corticosteroids, and anesthesia) can cause atypical location of worms.

Cysticercosis and Neurocysticercosis

Epidemiology and Etiology

Cysticercosis is considered a neglected parasitic infection by the CDC and is caused by the larval form of the tapeworm (cestode) *Taenia solium*. From 2003 to 2012, 18,600 neurocysticercosis-related hospitalizations were documented in the United States.[72] In disease-endemic countries, neurocysticercosis is the leading cause of acquired epilepsy.[73,74] The prevalence of neurocysticercosis in patients presenting to US emergency departments with seizures is estimated to be approximately 2%.[75] In the United States, the highest incidence of cysticercosis has been reported in immigrants from Mexico.[75] Comprehensive US epidemiologic data is scarce because cysticercosis is only a reportable disease in Arizona, California, New Mexico, Oregon, and Texas.

Pathophysiology and Clinical Presentation

Cysticercosis occurs from consumption of *Taenia solium* eggs that have been excreted from a *T. solium* tapeworm carrier. Intestinal tapeworm infection is a result of ingestion of poorly cooked pork that contains larvae or cysticerci. Cysticerci mature into adult tapeworms and attach to the small intestine via the scolex. The adult tapeworm produces approximately 1,000 proglottids that detach, migrate to the anus, and pass in the stool. Gravid proglottids release approximately 50,000 eggs in the feces.[76] Cysticercosis is a systemic disease caused by the larva of *T. solium* (oncosphere) and is usually acquired by ingestion of eggs in fecal-contaminated food or by autoinfection. The larvae penetrate the bowel and migrate through the bloodstream to infect different organs including the CNS (neurocysticercosis).[73,74] The larvae mature in about 8 weeks and remain as semitransparent, oval-shaped, fluid-filled cystin tissues. Cysticercosis in most tissues may not produce major symptoms and usually manifest as subcutaneous nodules, primarily in the arms, legs, and chest.

The most serious complication of cysticercosis is invasion of the CNS, which results in neurocysticercosis. Neurocysticercosis can cause obstructive hydrocephalus, strokes, and seizures. Epileptic seizures (50%-80%) may be the presenting symptoms in patients with neurocysticercosis.[76] Clinical presentation, primarily seizure history, together with radiographic demonstration (computed tomography and MRI) of the cysticerci within cysts in the CNS, is diagnostic for neurocysticercosis.[50] Serologic diagnosis is made by the use of an enzyme-linked immune transfer blot assay, which is considered highly sensitive and specific for cysticercosis.[77] Treatment recommendations are based on the location and appearance of the cysts on neuroimaging.

Treatment

⑦ Only neurocysticercosis is treated. The four approaches to neurocysticercosis management include surgery, symptomatic relief with corticosteroids, antiepileptic drug therapy, and antihelminthic therapy (Table e138-7). Antiparasitic therapy is often delayed until the patient's CNS symptoms are treated since antiparasitic drugs can worsen symptoms by inducing an inflammatory response. Fundoscopy should be performed in patients with potential hydrocephalus or cerebral edema and to exclude intraocular cysterci. Antihelminthic therapy is contraindicated in those with intraocular cysticerci due to risk of blindness with treatment. Patients with noncalcified parenchymal neurocysticercosis should initially receive symptomatic therapy with corticosteroids and antiepileptic drugs followed by antihelminthic therapy.[52] Albendazole with or without praziquantel is recommended based on how the patient is classified. Surgical management is often required for treatment of intraventricular neurocysticercosis.

TABLE e138-7

Treatment of Neurocysticercosis

	Corticosteroid Therapy	Antihelminthic Therapy
Parenchymal		
Nonviable calcified cysts +/− surrounding edema	Not routinely recommended	Not recommended
Single cystic or nodular enhancing lesion	Prednisone 1-2 mg/kg/day orally × 5-10 days	Albendazole 15 mg/kg/day orally divided into 2 doses × 7-14 days (maximum dose = 400 mg twice daily)
1-2 viable cysts seen as vesicular enhancing lesions +/− visible scolex	Dexamethasone 8 mg/day orally × 28 days; then taper down over 14 days	Albendazole 15 mg/kg/day orally divided into 2 doses × 10-14 days (maximum dose = 600 mg twice daily)
3 or more viable cysts seen as vesicular enhancing lesions +/− visible scolex	Dexamethasone 8 mg/day orally × 28 days; then taper down over 14 days	Albendazole 15 mg/kg/day orally divided into 2 doses × 10-14 days (maximum dose = 600 mg twice daily) ---**PLUS**--- Praziquantel 50 mg/kg/day orally divided into 3 doses × 10-14 days
Extraparenchymal		
Intraventricular cysts when surgical removal is contraindicated and a ventriculoperitoneal shunt is placed	Dexamethasone 8 mg/day orally × 14-28 days ---**OR**--- Prednisone 1-2 mg/kg/day orally × 14-28 days	Albendazole 15 mg/kg/day orally divided into 2 doses × 14 days (maximum dose = 400 mg twice daily)
Subarachnoid cysts in Sylvian fissure, basilar cisterns, or interhemispheric spaces	Following hydrocephalus management given 3-4 days before and throughout the duration of antihelminthic therapy: Prednisone 1 mg/kg/day orally ---**OR**--- Dexamethasone 0.2-0.4 mg/kg/day orally or IV	Albendazole 15 mg/kg/day orally divided into 2 doses (maximum dose = 600 mg twice daily) ---**OR**--- Albendazole 15 mg/kg/day orally divided into 2 doses (maximum dose = 600 mg twice daily) ---**PLUS**--- Praziquantel 50 mg/kg/day orally divided into 3 doses Duration of therapy is prolonged and depends on clinical and radiological response. Consultation with subject matter.

Data from References 73,75,78.

Evaluation of Therapeutic Outcomes

Weekly serum transaminases and a complete blood count with differential should be monitored for 2 to 4 weeks following the initiation of albendazole to evaluate for hepatotoxicity and leukopenia. For patients with noncalcified parenchymal neurocysticercosis, an MRI should be performed every 6 months to monitor for resolution of cystic lesions. Household contacts should be screened for *T. solium* carriage if the affected patient acquired neurocysticercosis from a nonendemic area or the affected patient does not report a history of having eaten undercooked pork.

Toxocariasis

Epidemiology and Etiology

Toxocariasis is a neglected parasitic disease that is caused by the nematode (canine roundworm) *Toxocara canis* and less commonly from the feline roundworm *T. cati*. Since it is a zoonotic parasite, most cases occur in children with exposure to playgrounds and sandboxes contaminated with dog and cat feces. Children who have dogs and cats as household pets are also at increased risk of disease. The reported United States *Toxocara* seroprevalence rates were approximately 5% using the National Health and Nutrition Examination Survey (NHANES III) data from 2011 to 2014, which is a decrease from previous estimates at around 12%.[78,79] The highest risk patient populations remain non-White, males, and lower socioeconomic status.

Pathophysiology and Clinical Presentation

Toxocara species infect dogs and cats and shed their eggs in feces. The eggs undergo embryonation over 1 to 4 weeks and are able to resist harsh environmental conditions to remain viable for months. Human toxocariasis occurs when humans ingest viable embryonated eggs in contaminated soil. After ingestion, *Toxocara* eggs hatch and release larvae, which disseminate and cause systemic symptoms.[80] Children may be at highest risk because of poor hand hygiene and ingestion of contaminated dirt in playgrounds and sandboxes.[81] Toxocariasis is commonly asymptomatic; the most common clinical syndromes are visceral larva migrans and ocular larva migrans. Visceral larva migrans most commonly affects children younger than 7 years old and typically causes hepatitis or pneumonitis as the larvae migrate from the intestine to the liver and lungs. A significantly higher prevalence of *T. canis* infection has been observed in those with asthma suggesting that toxocariasis may be associated with atopy.[82,83] Ocular larva migrans often is seen in older children and typically presents as unilateral vision loss. This is caused by granulomatous inflammation in response to the larvae migrating through the eye. Other manifestations include cutaneous disease, isolated eosinophilia, covert and common toxocariasis.[82,83] Leukocytosis, eosinophilia, and a positive Toxocara ELISA are typically seen with systemic disease. A Toxocara ELISA is recommended for diagnosis and a titer greater than or equal to 1:32 has a sensitivity of approximately 80% and greater than 90% specificity for diagnosing visceral toxocariasis and other forms of systemic toxocariasis.[80,81]

Treatment

The antihelminthic drugs albendazole and mebendazole are recommended for toxocariasis.[80,81] Neither drug is FDA-approved for this indication and the lack of large randomized controlled trials precludes definitive dosing and duration recommendations. Most sources recommend 5-day courses at standard doses. While the safety of albendazole in children younger than 6 years is unclear, the WHO recommends 200-mg doses for those at least 12 months of age. Mebendazole use is also limited in those younger than 2 years. Severe pulmonary, cardiac, neurologic disease and OLM should also be treated with concomitant anti-inflammatory therapy with corticosteroids, typically prednisone 0.5 to 1 mg/kg/day.[84]

ECTOPARASITES

Lice

Epidemiology and Etiology

A parasite that lives on the outside of the body of the host is called an *ectoparasite*. Three species of blood-sucking human lice belong to two genera: *Pediculus* and *Phtirus*. *Pediculus humanus capitis* causes head lice and *Pediculus humanus corporis* causes body lice. *Phthirus pubis* is a crab louse that causes pubic lice. These three infestations are collectively referred to as pediculosis. The human louse is detectable to the human naked eye and measures approximately 2 to 3 mm in length. Reliable data on the prevalence of lice in the United States are unavailable, but direct and indirect costs due to head lice may be as high as $1 billion per year.[85,86] Using pediculicide sales estimates in the United States, 6 to 12 million people per year may be affected, with girls likely affected more than boys.[87,88]

Pathophysiology and Clinical Presentation

Female lice deposit eggs on the hair. The eggs (or nits) remain firmly attached to the hair, and in about 10 days, the lice hatch to form nymphs, which mature in 2 weeks. Using both their piercing mouthparts and a pumping device, the larva and adults feed on the blood of the host.[87] The body louse and head louse are essentially identical, although they live on different parts of the body. Unlike the head louse, which lives on the hair, the body louse is more frequently found on clothing of the infected host.

Pubic or crab lice are found on the hair around the genitals, although they can occur in other areas of the body (eg, eyelashes, beards, and axillae). Patients usually complain of severe pruritus from papular lesions produced by the bite of the louse. Hypersensitivity to foreign material injected by the lice can produce macular swellings and occasionally can lead to secondary bacterial infections.

Treatment

⑧ For head lice, the American Academy of Pediatrics recommends either nonprescription 1% permethrin or pyrethrins plus piperonyl butoxide topical preparations as agents of choice unless local resistance to these agents is documented.[85] Permethrin is a derivative of the flowers of the plant *Chrysanthemum cinerariifolium*. The term *pyrethrin* is usually applied to several esters of chrysanthemic acid and pyrethric acid. Individuals who have a history of ragweed or chrysanthemum allergy should use pyrethrins with caution. The side effects reported with permethrin products are mild and include itching, burning, stinging, and tingling. Permethrin 1% is applied to the scalp after the hair has been dried following a shampooing. The scalp should be saturated with permethrin liquid, and a towel should be wrapped around the scalp to allow the application to stay on for 10 minutes. The hair then should be rinsed thoroughly. Permethrin and pyrethrins plus piperonyl butoxide should be used with nit combs because these agents are pediculocidal, but nonovidicidal. To ensure complete eradication, especially of newly hatched lice, it may be necessary to repeat the application since these drugs are not ovicidal.

Reports of lice resistance to nonprescription products, permethrin and pyrethrins, may make prescription-only spinosad 0.9% topical suspension the drug of choice for head lice as it is more effective than permethrin.[89,90] Spinosad is a semi-synthetic fermentation product of soil *Saccharopolyspora spinosa*. Its adverse effects may include erythema and irritation of the scalp. In addition to spinosad effectiveness in permethrin-resistant lice, nit combs are unnecessary because this drug kills both lice and their ova. Widespread use of spinosad as an alternative first-line agent may be limited by its prescription-only availability and higher cost compared to nonprescription permethrin.

Other topical preparations for lice are 0.5% malathion, 5% benzyl alcohol, and 0.5% ivermectin (Table e138-8).[85,87,89,90] Lindane 1% shampoo is no longer recommended because of neurotoxicity to humans.[85,90] Although not FDA-approved for head lice infection, oral ivermectin has been evaluated for this indication and it may have superior effectiveness compared to other topical treatment options.[92] It is well tolerated and may be an option for individuals who have experienced treatment failure. All agents except ivermectin may be used during pregnancy.[93] For the relief of pruritus, a soothing lotion of calamine liniment or lotion with 0.1% menthol may be used. Other members of the family should be treated. All bedding and clothes should be sterilized by boiling or washing in the hot water cycle of the washing machine to avoid reinfections. Seams of clothes should be examined to verify that all organisms are eradicated. An ocular lubricant (eg, Refresh Lacri-Lube) applied twice daily may be used to remove crab louse infection of the eyelids.

Scabies

Epidemiology and Etiology

Scabies is caused by the itch mite *Sarcoptes scabiei*, which affects both humans and animals. Mange in domestic animals is caused by the same organism. *S. scabiei* burrows under the skin and is transmitted through direct skin-to-skin contact for 15 to 20 minutes. The worldwide prevalence of scabies was over 200 million according to the Global Burden of Disease Study 2015.[94] The burden of scabies has decreased or remained stable over the past two decades across the world except in North America where a 24% increase was observed. Children less than 5 years old are most widely affected worldwide. The distribution of scabies is more evenly distributed across age groups in North America, but the majority of scabies cases continue to be diagnosed in children.[95]

Pathophysiology and Clinical Presentation

Infection usually affects the interdigital and popliteal folds, axillary folds, the umbilicus, and the scrotum (Fig. e138-2). Classic or typical scabies (scabies vulgaris) presents with severe itching and an inability to sleep and may have excoriations in the interdigital web spaces, wrists, elbows, buttocks, and groin with the face and neck unaffected. Atypical scabies include scalp scabies, crusted scabies (Norwegian scabies), and nodular scabies, all of which may occur in high-risk institutionalized or immunocompromised patients. Excoriations may lead to secondary bacterial infections, making scabies a major cause of impetigo. The diagnosis is made by looking for burrows formed by the mite and taking skin scrapings, which will demonstrate the mite on a wet mount. Typically, 10 to 15 mites may be present.

Treatment

⑨ These infections cause a great deal of discomfort and distress to patients and families. Therefore, the goals of therapy are to eradicate the infestations rapidly, to institute symptomatic treatment, and to provide counseling and reassurance. The CDC-recommended treatment of choice remains permethrin 5% cream despite concerns of increased resistance or oral ivermectin repeated in 2 weeks.[96,98] To initiate permethrin treatment, the skin should be scrubbed thoroughly in a warm soapy bath using a soft brush to remove all scabs. The lotion is then applied to the whole body, avoiding the face, mucous membranes, and eyes. The application should be left on for 8 to 14 hours before bathing. A single application of 5% permethrin results in cure rates in greater than 90% of subjects with scabies at 14 and 28 days, but a second dose should be applied 1 week later because its ovicidal efficacy remains unclear.[96,98] All close contacts should be checked and treated appropriately.

Other agents used to treat scabies include topical crotamiton 10% (Eurax) and oral ivermectin 200 mcg/kg as a single dose, which may be repeated in 2 weeks Table e138-8.[99] Crotamiton and oral ivermectin may be used in patients who have hypersensitivity to permethrin preparations. Topical corticosteroids and antihistamines may be used to decrease pruritus. There are no nonprescription drugs approved for treatment of scabies. Retreatment can be considered 2 weeks after initial treatment for patients who are still symptomatic or when live mites are present. Crusted scabies is more difficult to treat and may require combination therapy with oral ivermectin and a topical scabicide agent.

TABLE e138-8

Treatment of Ectoparasites

Drug	Ovicidal?	Resistance?	Lower Age or Weight Limit	Effectiveness	Dose
Head Lice					
Benzyl alcohol 5% lotion	No	No	6 months	75%	Apply to dry hair, leave on for 10 minutes then rinse; repeat in 7 days
Ivermectin 0.5% lotion	Partial (lice hatched from treated eggs die within 48 hours)	No	6 months	74%	Apply to dry hair and scalp, leave on for 10 minutes then rinse; one application is sufficient
Ivermectin oral tablet	Partial	No	15 kg	92%-97%	200 mcg/kg, two doses 7-10 days apart
Lindane 1% shampoo or lotion	Partial	Yes	6 months; 50 kg	70%-86%	Not recommended
Malathion 0.5% lotion	Partial	Not in the United States	6 years	80%-98%	Apply to dry hair until hair and scalp are wet, allow to dry naturally, shampoo 8-12 hours later, rinse and use a lice comb; repeat after 7-9 days only if live lice are still present
Permethrin 1% cream (OTC)	No	Yes	2 months	25%-50%	Apply to shampooed, towel-dried hair for 10 minutes, then rinse; repeat in 7 days
Pyrethrins with piperonyl butoxide shampoo (OTC)	No	Yes	2 months	62%	Apply to dry hair, leave on for 10 minutes then rinse; repeat in 7 days

Spinosad 0.9% suspension	Yes	No	6 months	85%-87%	Apply to dry hair, leave on for 10 minutes then rinse; repeat in 7 days only if live lice are present
Scabies					
Crotamiton 10% lotion	Yes	Yes	None	67%	Apply a thin layer to skin of the entire body from the neck down for 24 hours and then rinse off. Repeat application for another 24 hours.
Ivermectin oral tablet	Partial	Yes	15 kg	70%-95%	Take 200 mcg/kg orally, repeated in 2 weeks.
Lindane 1% lotion or cream	Yes	Yes	10 years	86%	Apply 1 oz of lotion or 30 g of cream in a thin layer to all areas of the body from the neck down and thoroughly washed off after 8 hours.
Permethrin 5% cream	Partial	Yes	2 months	90%-100%	Apply to all areas of the body from the neck down and wash off after 8-14 hours; apply a second dose 1 week later

SELF-ASSESSMENT QUESTIONS

1. Which one of the following antiparasitic drugs may be given as a single-dose to treat a 6-year-old child with giardiasis?

   A. Albendazole

   B. Benznidazole

   C. Mebendazole

   D. Metronidazole

   E. Tinidazole

2. Which one of the following is the greatest risk factor for contracting giardiasis?

   A. Drinking unpasteurized milk

   B. Eating undercooked pork

   C. Living near opossums

   D. Playing in outdoor sandboxes

   E. Swimming in contaminated water

3. Which of the following pairs matches the parasitic infection with the most effective preventative strategy?

   A. Malaria; mosquito avoidance

   B. Chagas disease; canine deworming

   C. Cysticercosis; unpasteurized dairy avoidance

D. Amebiasis; reduviid bug control

E. Cryptosporidiosis; good hand hygiene

4. JC is a 35-year-old man with HIV infection who presents with profuse, watery, nonbloody diarrhea. He stopped taking antiretroviral therapy 5 years ago and his most recent CD4+ T-cell count is 35 cells/mm^3 (35 × 10^6/L). Stool samples are collected and a *Cryptosporidium* direct fluorescent antibody test returns positive. JC should receive:

   A. Oral fluids and tinidazole

   B. Loperamide and nitazoxanide

   C. Opium tincture and metronidazole

   D. Antiretroviral therapy and nitazoxanide

   E. Antiretroviral therapy and metronidazole

5. Luminal agents that are recommended for patients with amebiasis who are asymptomatic cyst passers include:

   A. Iodoquinol and albendazole

   B. Iodoquinol and paramomycin

   C. Metronidazole and paramomycin

   D. Metronidazole and tinidazole

   E. Tinidazole and paramomycin

6. Tissue-acting agents that are recommended for patients with ALAs include:

   A. Iodoquinol and albendazole

   B. Iodoquinol and paramomycin

   C. Metronidazole and paramomycin

   D. Metronidazole and tinidazole

   E. Tinidazole and paramomycin

7. LL is a 52-year-old recent immigrant of Columbia who has been diagnosed with neurocysticercosis. *Taenia solium* cysts are found to be located in the basal meninges and in the fourth ventricles by MRI. Treatment of this patient may include surgical cyst removal, antiepileptic drugs, corticosteroids, and antihelminthic therapy. Which of these options may lead to worsening of neurocysticercosis symptoms?

   A. Phenytoin

   B. Metronidazole

   C. Dexamethasone

   D. Surgical cyst removal

   E. Albendazole and praziquantel

8. MC is a 4-year-old boy with fever, hepatosplenomegaly, abdominal pain, and wheezing who is diagnosed with toxocariasis. MC should receive:

A. Albendazole

B. Benznidazole

C. Fluconazole

D. Metronidazole

E. Tinidazole

9. TG is a 45-year-old man traveling to Kenya in 6 months. According to the Centers for Disease Control and Prevention (CDC) Yellow Book, the relative risk for malaria is moderate and chloroquine-resistant *P. falciparum* is prevalent. His current medications include lisinopril, duloxetine, and zolpidem as needed for insomnia. A recommended malaria chemoprophylaxis regimen is:

A. Doxycycline 100 mg orally once daily

B. Primaquine 30 mg base orally once daily

C. Mefloquine 228 mg base orally once weekly

D. Hydroxychloroquine 310 mg base orally once weekly

E. Atovaquone/proguanil 62.5 mg/25 mg orally once weekly

10. Severe falciparum malaria requires a patient to be admitted to an acute care unit and treated with:

A. Artesunate

B. Artemether-lumefantrine

C. Atovaquone-proguanil

D. Mefloquine

E. Quinine sulfate

11. An artemisinin-based regimen that may be used to treat uncomplicated chloroquine-resistant malaria includes:

A. Artesunate

B. Artemether-lumefantrine

C. Atovaqone-proguanil

D. Mefloquine

E. Quinine sulfate

12. RT is a 41-year-old Mexican man who has lived in California for the last 20 years and makes frequent trips to Guadalajara to visit his sisters. Two days ago, after he returned from a 3-week trip, he began complaining of fever, nausea, vomiting, and left eye swelling. He is diagnosed with Chagas disease (*Trypanosoma cruzi*). RT should receive:

A. Albendazole

B. Benznidazole

C. Metronidazole

   D. Nifurtimox

   E. Nitazoxanide

13. Chronic *Trypanosoma cruzi* infection or Chagas disease is likely to lead to:

   A. Asthma

   B. Cardiomyopathy

   C. Epilepsy

   D. Lactic acidosis

   E. Liver failure

14. An alternative prescription-only agent for *Pediculosis capitis* (head lice) in which permethrin resistance has been documented includes:

   A. Crotamiton 10% topical lotion

   B. Lindane 1% shampoo or lotion

   C. Spinosad 0.9% topical suspension

   D. Permethrin 5% topical cream

   E. Pyrethrins plus piperonyl butoxide shampoo

15. The drug regimen of choice for scabies treatment is:

   A. Crotamiton 10% topical lotion

   B. Lindane 1% shampoo or lotion

   C. Spinosad 0.9% topical suspension

   D. Permethrin 5% topical cream

   E. Pyrethrins plus piperonyl butoxide shampoo

SELF-ASSESSMENT QUESTION-ANSWERS

1. **E.** Tinidazole is the only single-dose regimen available for giardiasis treatment and accumulating evidence supports tinidazole as the 5-nitroimidazole of choice (see Table e138-2).

2. **E.** Like cryptosporidiosis, the greatest risk factor for giardiasis is ingestion of fecally contaminated water containing infective cysts (see subsection "Pathophysiology and Clinical Presentation" under section "Giardiasis").

3. **A.** Malaria results after *Plasmodium* sporozoites enter the host bloodstream following the bite of an infected female *Anopheles* mosquito. Mosquito avoidance is an effective strategy (see subsection "Chemoprophylaxis and Prevention" under section "Malaria"). Other causes of parasitic diseases may be further investigated after reviewing parasitic life cycles found in the section "Beyond the Book."

4. **D.** Antiretroviral therapy is essential for an effective treatment of cryptosporidiosis with nitazoxanide (see subsection "Treatment" under section "Cryptosporidiosis" and DHHS Guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents).

5. **B.** Paromomycin and iodoquinol remain in the lumen of the gastrointestinal tract and are used to eliminate *E. histolytica* cyst carriage (see Table e138-2).

6. **D.** Metronidazole and tinidazole are systemically absorbed and are used to treat amebic liver abscess (see Table e138-2).
7. **E.** Antiparasitic drugs are often delayed until CNS symptoms such as seizures are addressed because cyst destruction may lead to an acute exacerbation due to increased inflammation (see subsection "Treatment" under section "Cysticercosis and Neurocysticercosis" and Table e138-7).
8. **A.** Toxocariasis is treated with the antihelminthic drug albendazole (see subsection "Treatment" under section "Toxocariasis").
9. **A.** Either doxycycline or atovaquone-proguanil are recommended for chemoprophylaxis in chloroquine-resistant areas. The pediatric dose of atovaquone-proguanil 62.5 mg/25 mg is inappropriate for this 45-year-old man. Atovaquone-proguanil must also be given once daily (see Table e138-4).
10. **A.** Severe malaria falciparum should be treated with intravenous artusenate or intravenous quinidine gluconate (see Table e138-5 and Fig. e138-1).
11. **B.** Artemether-lumefantrine is the only oral artemisinin-based therapy listed (see Table e138-5 and Fig. e138-1).
12. **B.** Benznidazole is the only FDA-approved treatment for Chagas disease and is better tolerated than nifurtimox (see Table e138-2).
13. **B.** Early detection and treatment of Chagas disease is important because chronic infection with *T. cruzi* results in an irreversible cardiomyopathy (see subsection "Pathophysiology and Clinical Presentation" under section "Chagas Disease [American Trypanosomiasis]").
14. **C.** Topical spinosad may retain effectiveness in resistant lice and is considered to be both pediculocidal and ovicidal (see subsection "Treatment" under section "Lice").
15. **D.** Topical 5% permethrin cream remains the drug of choice for scabies (see subsection "Treatment" under section "Scabies").

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter e160: Myelodysplastic Syndromes

Jill S. Bates; Jolynn K. Sessions

KEY CONCEPTS

KEY CONCEPTS

① Myelodysplastic syndromes (MDS) primarily affect older adults.

② The exact cause of MDS is unknown and is probably multifactorial. MDS have been associated with host-specific characteristics, environmental, lifestyle, and therapeutic exposures.

③ Genomic instability drives MDS development and progression. The clonal population of cells manifested as MDS results from enhanced self-renewal of a hematopoietic stem cell or acquisition of self-renewal in a progenitor cell, increased proliferative capacity in the abnormal clone, impaired cell differentiation, evasion of immune regulation, and antiapoptotic mechanisms in the disease-sustaining cell.

④ Most patients with MDS present with fatigue, infection, bleeding/bruising, lethargy, or other symptoms related to cytopenias.

⑤ The prognosis of patients with MDS depends on the biology of the MDS and host characteristics. Overall survival time ranges from a few months to several years and is most accurately estimated with the International Prognostic Scoring System—Revised (IPSS-R).

⑥ The goals of therapy for MDS are to change the natural history of the disease, reduce the number of red blood cell transfusions, and improve quality of life.

⑦ Lenalidomide should be considered for patients with MDS that harbor a del(5q) clone and is particularly beneficial in those with symptomatic anemia.

⑧ Patients with lower-risk MDS and symptomatic anemia who have a serum erythropoietin level ≤500 mU/mL (U/L) are suitable candidates for an erythropoiesis stimulating agent with or without growth factor support.

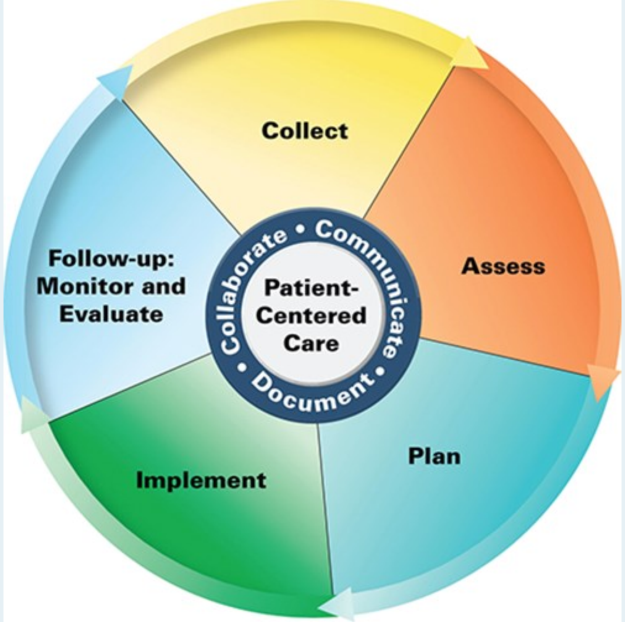
⑨ A subset of lower-risk MDS patients respond well to antithymocyte globulin (ie, immunosuppressive therapy), which is most effective in patients who have a hypocellular marrow, MDS that expresses HLA DR15 with trisomy 8 as the sole cytogenetic abnormality, refractory anemia, and younger than 60 years.

⑩ Further evaluation is required to determine the optimal hypomethylating agent treatment regimen.

⑪ Allogeneic hematopoietic stem cell transplantation offers potentially curative therapy to patients with MDS who have a donor and are healthy enough for the procedure.

PATIENT CARE PROCESS

Patient Care Process for Myelodysplastic Syndromes



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient chief complaint (eg, fatigue, easy bruising)
- Patient characteristics (eg, age, sex, pregnant, weight)
- Patient medical history (personal including blood transfusion history, sexual history, reproductive history including whether the patient is still menstruating and has her uterus (if female), and family history minimum of 3 generations)
- Social history (eg, tobacco/ethanol use), employment status, and history
- Current medications including over-the-counter aspirin/nonsteroidal anti-inflammatory drug use, herbal products, dietary supplements, and prior chemotherapy, radiotherapy, or granulocyte colony-stimulating factor
- Full review of systems (objective data)
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight
    - Labs including complete blood count with differential, peripheral blood smear, reticulocyte count, serum vitamin B_{12}, RBC folate and copper, HIV, TSH, ferritin, iron, TIBC, LDH
    - Bone marrow biopsy procedure: morphologic evaluation, karyotyping, consider molecular genetic evaluation for TP53, ASXL1, etc.
    - Serum erythropoietin level (for lower risk MDS)

Assess

- Karyotype, cytogenetics as well as any identified somatic mutation, degree of cytopenias, and percentage of blasts
- Determine the WHO subtype of MDS according to the 2016 guidelines and the IPSS-R category of risk
- Determine if molecularly guided therapy (ie, deletion 5q) and lenalidomide or immunosuppressive therapy (for patients who are ≤60 years old, shorter duration of red cell transfusion dependence, over-representation of the class II histocompatibility antigen DR15 [HLADR15], <5% blasts, and normal cytogenetics) is indicated
- Based on a review of systems, determine if symptoms related to anemia are present; patient-specific factors (eg, performance status and ability to tolerate treatment); and eligibility for allogeneic HSCT

Plan*

- Develop a treatment plan based on risk category (lower risk vs higher risk), cytogenetics and eligibility for allogeneic HSCT
- Monitoring parameters including efficacy (eg, CBC with differential, history, physical examination) and safety (eg, sign and symptoms of toxicities or complications); frequency and timing of follow-up should be individualized

- Patient education (eg, purpose of treatment, treatment schedule (cycles, days), safe handling, reproduction and sexual precautions, administration, adverse drug reactions and their management)
- Review self-monitoring plan for the need to call the cancer care team or proceed to the nearest emergency department as well as home management of adverse drug reactions and complications where possible

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, infusion appointments where applicable, blood count evaluation, chemistries, history, and physical examination)

Follow-up: Monitor and Evaluate*

- For patients on chemotherapy, evaluations should occur with each cycle
- Restoration of hematopoiesis as evidenced by normalization in CBC with differential
- Evaluate for signs and symptoms of anemia, bleeding, or infection
- Morphologic, cytogenetic, and molecular normalization in bone marrow biopsy sample evaluations
- Patient adherence to treatment plan based on multiple sources of information

**Collaborate with patient, caregivers, and other healthcare professionals.*

INTRODUCTION

Myelodysplastic syndromes (MDS) are a heterogeneous group of myeloid stem cell disorders that are clonal in nature and characterized by ineffective hematopoiesis with morphologic dysplasia in hematopoietic cells and peripheral cytopenias.[1] About one-third of patients with MDS will have a disease course that progresses to acute myeloid leukemia (AML). The diagnostic criteria for MDS is the presence of bone marrow dysplasia in at least 10% of cells in one or more of three major bone marrow lineages. Additionally, a diagnosis of MDS can be achieved if 5% to 19% blasts or an MDS-associated karyotype is noted in the bone marrow.[1–3] The clinical course of patients with MDS varies from a slowly progressing, indolent disease, to more aggressive disease characterized by excess bone marrow blasts and rapid progression to AML.[2,3]

Our understanding of the molecular biology behind MDS has advanced in recent years, but few targeted treatments have been approved in MDS. Aberrations in epigenetic regulator genes, spliceosome component pathways, DNA damage response genes, and genes regulating transcription factors have redefined the molecular landscape in MDS.[4] Chromosomal abnormalities have been incorporated into prognostic models predicting survival and leukemic transformation.[2,3] Several agents exist to treat MDS, and are generally selected based on severity of disease and prognostic factors.[2] Despite progress in disease classification, identification of over 40 recurrently mutated genes, improvement in risk stratification, and development of new treatment options in the past two decades, few personalized treatment options are available.

EPIDEMIOLOGY

① MDS primarily affects older adults with a median age at diagnosis of 76 years and a slight male predominance (ie, male-to-female ratio of about 1.75 to 1).[2] An estimated 3 to 12 cases of MDS are diagnosed per 100,000 persons/year.[5] The risk of MDS increases with age, most commonly occurring in the seventh and eighth decade of life.[2,5] It is difficult to accurately determine the prevalence of MDS but recent reports suggest that the prevalence of MDS has been grossly underestimated and as many as 60,000 people with MDS live in the United States.[2] Many experts predict that the incidence of MDS will increase as the population of the United States ages and clinicians become more aware of MDS.

ETIOLOGY

② The exact cause of MDS is unknown and is probably multifactorial. MDS have been associated with host-specific characteristics, lifestyle, environmental, and therapeutic exposures (medical treatments or radiation).[6,7] A small proportion of the MDS population has a genetic predisposition.[6,7] Several well-characterized inherited syndromes can increase the risk of developing MDS or acute leukemia.[7] For example, telomere biology disorders, bone marrow failure syndromes (eg, Fanconi anemia, Shwachman-Diamond syndrome, dyskeratosis congenita), which often manifest in childhood, and Down syndrome. In addition, familial MDS/Acute Leukemia predisposition syndromes as the most common presenting feature have been recognized. Familial genetic information may have implications on the treatment of MDS, for example, if allogeneic hematopoietic stem cell transplant is indicated.

Another host characteristic associated with an increased risk of developing MDS is senescence. With age, an individual's hematopoietic stem cell (HSC) population has a reduced capacity for self-renewal. In addition, HSCs become more clonal in nature as one ages and have a bias toward myeloid cells. Clonal hematopoiesis of indeterminate potential (CHIP) occurs when hematopoietic stem/progenitor cells divide and accumulate recurrent somatic mutations that generally do not affect function and are common in MDS and AML.[8] These myeloid clones may contain disease causing or epigenetic changes that increase an individual's risk of developing MDS. Modifiable host risk factors for MDS include smoking and obesity.[2] Lastly, chronic immune stimulation or therapy to manage infectious and autoimmune diseases in a given host increases the risk for development of MDS.

Environmental exposure to agricultural chemicals (eg, pesticide) has been associated with an increased risk of developing MDS.[9] MDS have also been linked in a dose-dependent relationship to ionizing radiation in atomic bomb survivors in Japan and have been reported in workers in the Chernobyl nuclear accident.[10] Further, occupational exposures to hair dyes, cereal dust, exhaust gases, diesel fuel, and industrial solvents (including benzene and toluene) have been associated with the development of MDS.

Therapy-related myeloid neoplasms (TR-MN) are designated by the World Health Organization as a distinct subgroup.[1] TR-MNs can be further divided into therapy-related MDS or AML (t-MDS or t-AML1). About 10% to 20% of all cases of MDS and acute leukemia are attributed to therapies such as radiation, chemotherapy, or both. Patients who receive intensive chemotherapy regimens have an increased risk of TR-MNs that is 4.7-fold higher than the general population.[2] Since 1975, there has been a noted increase in the risk of TR-MNs after treatment for non-Hodgkin lymphoma over time. In contrast, a decreased risk of developing TR-MNs over time has been observed after therapy for multiple myeloma and ovarian cancer since 1975. In addition, newly observed risk in patients with sarcoma, cervical, prostate, esophageal, endometrial, and possibly anal cancers have emerged. Trends in risk for developing TR-MNs have coincided with treatment patterns for a given malignancy.[10] For example, melphalan was once used routinely to treat multiple myeloma but has fallen out of favor. The risk for developing t-MDS increases with age, higher doses of chemotherapy or radiation, longer duration of exposure, and exposure to both chemotherapy and radiation.[2] Chromosomal abnormalities are found in about 90% of t-MDS compared with 50% to 60% of *de novo* MDS.[11] t-MDS has an increased risk of progression to AML and a poorer prognosis than *de novo* MDS.

Several chemotherapeutic agents have been associated with t-MDS (Table e160-1). The contribution of a specific agent is difficult to assess because patients are usually exposed to multiple agents, often in combination with radiation. The most frequently reported classes of chemotherapeutic agents associated with t-MDS are alkylating agents and topoisomerase II inhibitors.[12]

TABLE e160-1

Therapies Associated with Therapy-Related Myelodysplastic Syndromes

Alkylating Agents	Topoisomerase II Inhibitors	Miscellaneous
Busulfan	Dactinomycin	Azathioprine
Carmustine	Daunorubicin	Carboplatin
Chlorambucil	Doxorubicin	Cladribine
Cyclophosphamide	Epirubicin	Cisplatin
Dacarbazine	Etoposide	Docetaxel
Ifosfamide	Idarubicin	Fludarabine
Lomustine	Mitoxantrone	Iodine-131 tositumomab
Mechlorethamine	Teniposide	Mercaptopurine
Melphalan		Methotrexate
		Mycophenolate
		Paclitaxel
Mitomycin		Vinblastine
Procarbazine		
Temozolomide		Vincristine
Thiotepa		Vindesine
		Yttrium-90 ibritumomab tiuxetan

Data from References 12-16.

The role of alkylating agents in the development of t-MDS is well established in patients with cancer and those receiving high cumulative doses of alkylating agents for autoimmune disorders such as rheumatoid arthritis.[12] The latency period between exposure to alkylating agents and the development of t-MDS is about 4 to 7 years. Characteristic chromosomal abnormalities in t-MDS associated with alkylating agents include deletions on chromosomes 5 and 7.

Topoisomerase II inhibitors, including the epipodophyllotoxins (etoposide and teniposide), anthracyclines (daunorubicin, doxorubicin, epirubicin, idarubicin), and the anthracenedione mitoxantrone, are also associated with t-MDS.[12] t-MDS associated with topoisomerase II inhibitors typically occur a median of 2 to 3 years after exposure, and patients are more likely to present with AML at diagnosis. Chromosomal abnormalities often found in patients with t-MDS associated with topoisomerase II inhibitors include balanced translocations involving the *MLL* gene 11q23 and 21q22.

Y-ibritumomab tiuxetan is a monoclonal antibody linked to a radioactive isotope (ie, radioimmunoconjugate). Another agent, iodine-131 tositumomab, is no longer commercially available. These radioimmunoconjugates deliver radiation to the antibody-bound targeted cell and to neighboring cells through a “cross-fire” effect. TR-MNs are reported to occur in 5% to 10% of patients exposed to iodine-131 tositumomab and in 1% to 5% of patients exposed to Y-ibritumomab tiuxetan.[13–15] About 8% of patients receiving myeloablative doses of ibritumomab tiuxetan as part of their conditioning regimen before hematopoietic stem cell transplantation (HSCT) developed TR-MNs, similar to the rate in patients receiving myeloablative chemotherapy-based conditioning regimens.[14] Radioimmunoconjugates are primarily used to treat non-Hodgkin lymphoma, a patient population likely to receive other therapies associated with t-MDS, including alkylating agents, anthracyclines, and radiation. Therefore, it is difficult to determine the additional risk for TR-MNs due solely to exposure to one of these agents.

Two systematic reviews have been conducted to evaluate the impact of granulocyte colony-stimulating factors used during treatment of adults with solid tumors and lymphoma on all-cause mortality and secondary malignancies.[17,18] Both of these studies reported reduced all-cause mortality in patients treated with granulocyte colony-stimulating factors, likely as a result of increased ability to use dose-dense chemotherapy. However, both systematic reviews showed an increased risk of secondary malignancies including t-MDS. It is not clear whether the increased risk of secondary malignancies was due to either the use of granulocyte colony-stimulating factor or dose-dense chemotherapy. In contrast, clonal evolution was not observed in aplastic anemia patients treated with granulocyte colony-stimulating factors.[18] Benefit-to-risk evaluation continues to be important when the use of granulocyte colony-stimulating factors is considered.

Patients undergoing autologous HSCT are at increased risk for the development of t-MDS. Conditioning regimens given before HSCT usually include high doses of alkylating agents or etoposide, sometimes in combination with total body irradiation. As many as 8% to 20% of patients with non-Hodgkin lymphoma treated with autologous HSCT will develop t-MDS within 10 years of transplantation.[19,20] Risk factors for development of t-MDS after autologous HSCT include antecedent conventional chemotherapy, prior radiation therapy, low stem cell dose, older age at time of transplant, and use of total body irradiation in the conditioning regimen.[19,20]

PATHOPHYSIOLOGY

③ Knowledge of normal hematopoiesis is needed to understand the pathophysiology of MDS (see Chapter e106 for a more detailed description of hematopoiesis). Diverse pathophysiology underlying MDS causes heterogeneity in clinical presentation, pattern of disease progression, and response to therapy. Further, the pathogenesis of MDS has not been fully elucidated.[2] Progressive bone marrow failure is characteristic of patients with MDS and is the result of ineffective hematopoiesis. In addition to peripheral blood cytopenias, the terminally differentiated cells that are produced may have functional defects. Neutrophils may have reduced bactericidal and fungicidal activity despite a normal quantity.[21] Platelets may be normal in quantity but have impaired activation, secretion, and aggregation.[22] It may seem odd that MDS is a clonal disease with a phenotype that includes cytopenias, but impairment of terminal differentiation and increased apoptosis explain this phenomenon.

A multistep model for the pathogenesis of MDS has been proposed and the disease can arise via multiple different pathways.[2] Recurrent somatic mutations drive MDS development and progression. The clonal population of cells manifested as MDS results from enhanced self-renewal of a HSC or acquisition of self-renewal in a progenitor cell, increased proliferative capacity in the abnormal clone, impaired cell differentiation, evasion of immune regulation, and antiapoptotic mechanisms in the disease-sustaining cell. The abnormal clone proliferates or evades apoptosis because of genomic instability and abnormalities in cytokines and the bone marrow stroma. These changes create a dysplastic, clonal population of cells in a milieu unable to support normal hematopoiesis.

Genomic Instability

MDS is clonal in nature and is preceded by the acquisition and expansion of genetic alterations. The diagnosis of MDS is not based on a defining mutation or single inciting genetic alteration but a genomic fingerprint is emerging. Chromosomal abnormalities, most often genomic losses and gains, are detected by cytogenetic analysis in approximately 45% of patients with *de novo* MDS and remain one of the strongest determinants of prognosis.[2] Multiple cytogenetic abnormalities that correlate with the clinical course of MDS were incorporated in the original International Prognostic Scoring System (IPSS) classification and prognostic assessment, including 5q or 20q deletions and chromosome 7 abnormalities.[2] The International Prognostic Scoring System—Revised [IPSS-R] includes several additional cytogenetic abnormalities that correlate with the clinical course of MDS such as trisomy 8 or 19, 12p, or 11q deletions, and double abnormalities.[3] Deletions on chromosome 5q occur in up to 12% of patients and are of particular interest because multiple genes involved in hematopoiesis are located there.[11] In addition, MDS with 5q deletions as the sole genetic aberration is recognized as a distinct subtype of MDS with a favorable prognosis and a high likelihood of response to lenalidomide.[1,11,23]

Emerging data about somatic mutations found in MDS have the potential to allow clinicians to provide personalized therapy.[24] The most frequently mutated MDS genes (>5%) are *SF3B1, TET2, ASXL1, SRSF2, DNMT3A, RUNX1, U2AF1, ZRSR2, STAG2, TP53, NRAS*, and *EZH2*.[4] Some of these mutations are associated with prognosis, including *SF3B1* (more favorable prognosis) and *ASXL1, SRSF2, DNMT3A, RUNX1, U2AF1, ZRSR2, TP53, NRAS* and *EZH2* (poor prognosis).[2,24] Frequently mutated genes in MDS suggest a disease of disordered spliceosome function and epigenetic regulation.

Somatic mutations occur in five major categories: RNA splicing, DNA methylation, histone modification, activated cell signaling, and myeloid transcription factors. At least 90% of patients with MDS will harbor at least one somatic mutation from a set of about 40 recurrently mutated MDS genes.[2] Furthermore, some somatic mutations are associated with prognosis and they can be used to better understand the clonal architecture of MDS. Unfortunately, a similar spectrum of somatic mutations can be seen in older patients without dysplasia. Therefore, DNA sequencing cannot completely replace morphologic evaluation for the diagnosis of MDS at this time.

Mutations within components of the spliceosome, the unit within eukaryotic nuclei that splices introns from pre-mRNA, occur in up to 60% of cases and are the most common recurrent lesions in MDS.[4,24] Splicing mutations are associated with ring sideroblast morphology, lower-grade disease, and better prognosis.[24] The splicing mutation *SF3B1* is the most common spliceosome alteration in MDS.

The splicing factors and epigenetic modifiers *DNMT3A* and *TET2* tend to be mutated early in the evolution of MDS.[2] The term *epigenetics* refers to mechanisms that regulate the expression of DNA without affecting its sequence. Epigenetic changes, including DNA methylation (*TET2, DNMT3*) and histone modification (*ASXL1, EZH2*) among many others, have been identified in numerous malignancies but are of particular importance in MDS.[24]

DNA methylation is the best described and most common epigenetic marker. In the mammalian genome, only cytosine located 5′ to a guanosine (CpG) can be methylated (CpG pair). Clusters of CpG pairs, known as *CpG islands*, are near the promoter regions for many genes. These regions are unmethylated in normal cells, allowing for standard DNA expression to occur. Increased methylation (hypermethylation) of *CpG* islands occurs via DNA methyltransferases and is associated with aberrant gene silencing, which may lead to further genetic instability and cell cycle dysfunction. Demethylation (hypomethylation), regulated by *TET2*, may lead to reexpression of previously silenced genes.[24] Hypermethylation and gene silencing have been identified in patients with MDS, and azacitidine and decitabine reverse this process.[25]

Histone modification is another significant epigenetic marker in MDS. Histones coil with DNA to form tightly wound complexes called chromatin. Posttranslational modifications of histones, by acetylation, methylation, and ubiquitination can alter the structure of chromatin creating opportunities for gene suppression or expression, depending on the structural change of the chromatin. *ASXL1*, an epigenetic regulator of chromatin modification, has been identified as the third most commonly mutated gene in MDS, occurring in 15% to 25% of MDS patients and is independently associated with worse overall survival.[24] Histone hypoacetylation has been documented in malignant cells and several histone deacetylase inhibitors have been studied in patients with MDS as monotherapy, in combination with hypomethylating agents or with low-dose cytarabine in an attempt to promote histone acetylation and expression of previously suppressed tumor suppressor genes.[26–29]

Genes that encode for proteins involved in cell signaling cascades can be mutated in MDS, although this is more frequently observed in AML.[2] The pathways impacted are those that often promote cell proliferation. Many of these mutations affect the cell through the MAPK pathway (ie, NRAS, KRAS, NF1, and PTPN11). When these mutations occur in MDS, they typically arise late in disease evolution. Mutations in NRAS are associated with a poor prognosis in MDS.[2]

Transcription regulation genes can be mutated in MDS. Examples include *TP53, RUNX1, GATA2*, and *MECOM*.[2] *TP53* mutations occur in about 5% of MDS cases and in greater than 30% of TR-MNs. *TP53* mutations can adversely affect the prognosis in all subtypes of MDS.[4] *TP53* mutations are generally associated with low platelet levels, high blast count, prior exposure to chemotherapy, and complex cytogenetics.[2]

Some studies suggest that *TP53* mutations may sensitize cancer cells to hypomethylating agents like decitabine. In a study of 84 patients with AML or MDS, response rates after 10-day courses of decitabine were significantly higher among patients with mutated *TP53* when compared with wild-type *TP53*.[29] The authors concluded that 10-day courses of decitabine for AML or MDS in patients who had mutations in *TP53* had better responses. However, other experts disagreed with this conclusion citing other studies that found no difference in response rates to decitabine when comparing *TP53* mutated disease to wild-type *TP53* disease.[30]

Bone Marrow Microenvironment and Immune System Dysregulation

The myelodysplastic clone is associated with cellular dysfunction, including excess secretion of cytokines, defective differentiation, genomic instability, and reduced response to regulatory cytokines.[2] Bone marrow cells often have a paradoxically high rate of cellular division and are generally normocellular or hypercellular for age. Apoptosis, or programmed cell death, is increased leading to the futile cycling of precursor cells and impaired production of mature peripheral blood cells. Overproduction of proapoptotic and inflammatory cytokines and vascular endothelial growth factor may contribute to this process.[2] Bone marrow stromal cells from MDS patients show decreased ability to support normal hematopoietic cell function.

Patients with MDS frequently have evidence of immune dysregulation, such as impaired immune surveillance and autoimmune reactions. Cytopenias can be related to an autoimmune T-cell–mediated response. A subset of MDS patients characterized by younger age, refractory anemia of short duration, a hypocellular bone marrow, trisomy 8 as the sole cytogenetic abnormality, and expression of human leukocyte antigen (HLA) haplotype DR15 have a high likelihood of response to immunosuppressive therapy.[2] Cyclosporine and antithymocyte globulin may induce durable responses in this subgroup of patients, confirming the role of immune dysregulation. Whether B-cells and T-cells are a part of the MDS clonal population or a secondary reaction after the development of the malignant clone is unclear.

CLASSIFICATION AND PROGNOSIS

Different strategies to identify phenotypes of MDS based on the heterogeneous biology observed within the disease have evolved over time. The French-American-British (FAB) classification established subgroups of MDS based on morphology of bone marrow aspirates and peripheral blood blast percentage. The FAB classification system was replaced in 2008 by the WHO classification system, which also incorporates whether dysplasia or cytopenias affect a single-cell lineage or multiple myeloid cell lines and cytogenetics.[31] A revision of the WHO classification was published in 2016 with changes to simplify classification and define the role of molecular genetic testing (Table e160-2).[1]

TABLE e160-2

2016 World Health Organization Classification of Myelodysplastic Syndrome

Classification	Blood[a]	Bone Marrow
MDS with single lineage dysplasia	1-2 cytopenia(s) No or rare blasts (<1%)	1 dysplastic lineage <5% blasts <15% ringed sideroblasts
MDS with multilineage dysplasia	1-3 cytopenia(s) No or rare blasts (<1%)	Dysplasia in 2-3 myeloid cell lines <15% ringed sideroblasts <5% blasts
MDS with ringed sideroblasts (single or multilineage dysplasia)	1-3 cytopenia(s) No or rare blasts (<1%)	Dysplasia in 1-3 myeloid cell lines <5% blasts +15% ringed sideroblasts
MDS with isolated del(5q)	1-2 cytopenia(s) No or rare blasts (<1%)	1-3 dysplastic lineages <5% blasts Del(5q) alone or with 1 additional a bnormality except −7 or del(7q)
MDS with excess blasts	1-3 cytopenia(s) 2%-19% blasts ± Auer rods	0-3 dysplastic lineages 5%-19% blasts ± Auer rods
MDS, unclassifiable	1-3 cytopenias <1% blasts	0-3 dysplastic lineages 0 or <15% ringed sideroblasts <5% blasts MDS defining karyotype

[a] Cytopenias are defined as hemoglobin <10 g/dL (100 g/L; 6.21 mmol/L), platelet count <100 × 10^9/L (100,000/mm^3), and absolute neutrophil count <1.8 × 10^9/L (1,800/mm^3).

Data from Reference 1.

⑤ Models to predict overall survival and risk of transformation to AML continue to be developed and refined as new information about the genetic basis of MDS evolves. Based on an observational study of mostly untreated MDS patients, the IPSS was developed to identify factors that would predict the progression of MDS.[2] Multivariate analyses identified four prognostic factors: cytogenetic abnormalities, percentage of bone marrow blasts, age, and number of cytopenias. Using these four factors, researchers were able to stratify patients into four risk groups that correlated with overall survival, which ranged from a few months to several years (Table e160-3).

TABLE e160-3

International Prognostic Scoring System for Myelodysplastic Syndromes

	Score Value				
Prognostic Variable	**0**	**0.5**	**1**	**1.5**	**2**
Bone marrow blasts (%)	5	5-10	—	11-20	21-30
Karyotype	Good	Intermediate	Poor		
Cytopenia	0 or 1	2 or 3			
Cytopenia: Absolute neutrophil count <1,800 cells/mm^3 (1.8 × 10^9/L) Hemoglobin <10 g/dL (100 g/L; 6.21 mmol/L) Platelet count <100,000 cells/mm^3 (100 × 10^9/L)					
Karyotype: Good: normal, isolated 5q deletion, isolated 20q deletion, Intermediate: any other abnormalities Poor: trisomy 7, complex or >3					

Score	**Risk Group**	**Median Survival (years)**
0	Low	5.7
0.5-1	Intermediate-1	3.5
1.5-2.0	Intermediate-2	1.2
≥2.5	High	0.4

Data from Reference 2.

The IPSS-R was developed after analysis of more than 7,000 patients whose disease had not been treated with disease-altering therapy (Table e160-4).[3] This model differs from the IPSS in that it identifies five risk categories by incorporating different groupings for marrow blast percentage value and depth of cytopenias. This expands the cytogenetic risk groups from three to five and includes a number of less common cytogenetic abnormalities. Patient age, performance status, serum ferritin, and lactate dehydrogenase levels were additional significant predictors for survival, but not for AML transformation.

TABLE e160-4

International Prognostic Scoring System—Revised for Myelodysplastic Syndromes

Prognostic Variable	0	0.5	1	1.5	2	3	4
Cytogenetics*	Very good		Good		Intermediate	Poor	Very poor
Bone marrow blast (%)	≤2		>2-<5		5-10	>10	
Hemoglobin (g/dL)	≥10 (100 g/L; 6.21 mmol/L)		8-<10 (80-100 g/L; 4.97-6.21 mmol/L)	<8 (80 g/L; 4.97 mmol/L)			
Platelets (cells/mm^3)	≥100,000 (100 × 10^9/L)	50,000-<100,000 (50-<100 × 10^9/L)	<50,000 (50 × 10^9/L)				
Absolute neutrophil count (cells/mm^3)	≥800 (0.8 × 10^9/L)	<800 (0.8 × 10^9/L)					

*Karyotype: Very good: Y, del(11q).

Good: normal, del(5q), del(12p), del(20q), double including del(5q).

Intermediate: del(7q), +8, +19, i(17q), any other single or double independent clones.Poor: 7, inv(3)/t(3q)/del(3q), double, including 7/del(7q); complex: three abnormalities.Very poor: complex: >3 abnormalities.

Score	Risk Group	Median Survival (years)
≤1.5	Very low	8.8
>1.5-3	Low	5.3
>3-4.5	Intermediate	3
>4.5-6	High	1.6
>6	Very high	0.8

Data from Reference 3.

Recent reports have demonstrated that recurrent somatic gene mutations predict prognosis independent of the IPSS score, and their incorporation into a risk classification scheme does enhance the model.[2,32] About half of patients with MDS have normal cytogenetics. After the full spectrum of somatic mutations in MDS has been defined, prognostic scoring systems will need to incorporate relevant molecular features.

The IPSS and the IPSS-R are prognostic systems applied at diagnosis and the systems most widely used in clinical trials. However, patients with MDS can have disease biology that changes over time. Some of these changes may impact risk. Two prognostic systems have been developed that are more dynamic (ie, they can be applied beyond the time of diagnosis) are the World Health Organization Prognostic Scoring System (WPSS) and the global MD Anderson Cancer Center (MDACC) lower risk prognostic scoring system.

The WPSS was created in 2007. Part of its original criteria included whether the MDS patient was transfusion-dependent or not, and some experts thought this criterion was too subjective. In 2011, the WPSS was revised to address the criticism by adding hemoglobin thresholds of 11 g/dL (110 g/L; 6.83 mmol/L) in males and 9 g/dL (90 g/L; 5.59 mmol/L) in females.[2] The WPSS system classifies patients into five-risk groups with different survival and probability of leukemic evolution. The WPSS was compared to the IPSS-R.[33] The two prognostic systems were in agreement with discrepancies mainly occurring in early stage disease. Further, the WPSS placed more weight on degree of anemia when compared with the IPSS-R.[33] It is anticipated that the addition of somatic mutation data to WPSS and the IPSS-R will improve their accuracy and clinical utility.

Low-risk MDS patients have significant biological variability that may not be adequately considered in current prognostic systems. The MD Anderson Cancer Center developed the lower-risk scoring system for MDS.[33] In that system, MDS patients with low-risk disease had a more unfavorable prognosis within this risk group if they had unfavorable cytogenetics, age ≥ 60 years old, anemia, low platelet counts, or ≥ 4% blasts.[33] While this is a validated prognosis classification system, it is not widely used in clinical practice.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Myelodysplastic Syndromes

General

- Patients with MDS may develop isolated anemia (hemoglobin less than 11 g/dL [110 g/L; less than 6.83 mmol/L]), neutropenia (less than 1,500 cells/mm^3 [1.5×10^9/L]), or thrombocytopenia (less than 100,000 cells/mm^3 [100×10^9/L]) or multiple peripheral cytopenias
- Patients may be asymptomatic, with cytopenia(s) discovered on complete blood count with differential
- A thorough transfusion history should be obtained upon diagnosis of MDS

Symptoms

- ④ If symptomatic, the patient may report fatigue, lethargy, malaise, palpitations, dyspnea on exertion, exercise intolerance, or other symptoms associated with hypoxia secondary to anemia
- Patients may have symptoms of infection, including cough or dysuria
- Patients may present with complaints of easy bruising or bleeding

Signs

- Pallor, tachycardia, or tachypnea related to anemia
- Fever, chills, rigors caused by infection and immune dysfunction
- Petechiae, bruising, epistaxis, gingival bleeding, excessive vaginal bleeding, bruising, or hematuria caused by thrombocytopenia

Laboratory Tests

- Complete blood count with differential
- Anemia often is macrocytic or normocytic with a low reticulocyte index
- Serum vitamin B_{12}, red blood cell (RBC) folate, and copper levels
- Testing for the human immunodeficiency virus (HIV)
- Serum thyroid-stimulating hormone
- Serum erythropoietin (EPO) level
- Serum ferritin, iron, and total iron-binding capacity
- Peripheral blood smear
- Lactate dehydrogenase level

Other Diagnostic Tests

- Bone marrow biopsy and aspirate: morphologic examination, cytochemical staining, immunophenotyping, and cytogenetics (chromosome analysis)
- Consider MDS-relevant molecular genetics testing

Criteria for Diagnosis

- Stable cytopenia for at least 6 months (2 months if accompanied by a specific karyotype associated with MDS or bilineage dysplasia)
- Exclusion of other causes of cytopenia or dysplasia
- One of the following:
  1. Dysplasia (more than 10% in one or more of three major bone marrow lineages)
  2. Blast cell count of 5% to 19%
  3. Specific MDS-associated karyotype (eg, del(5q), del(20q), +8, or del(7q))

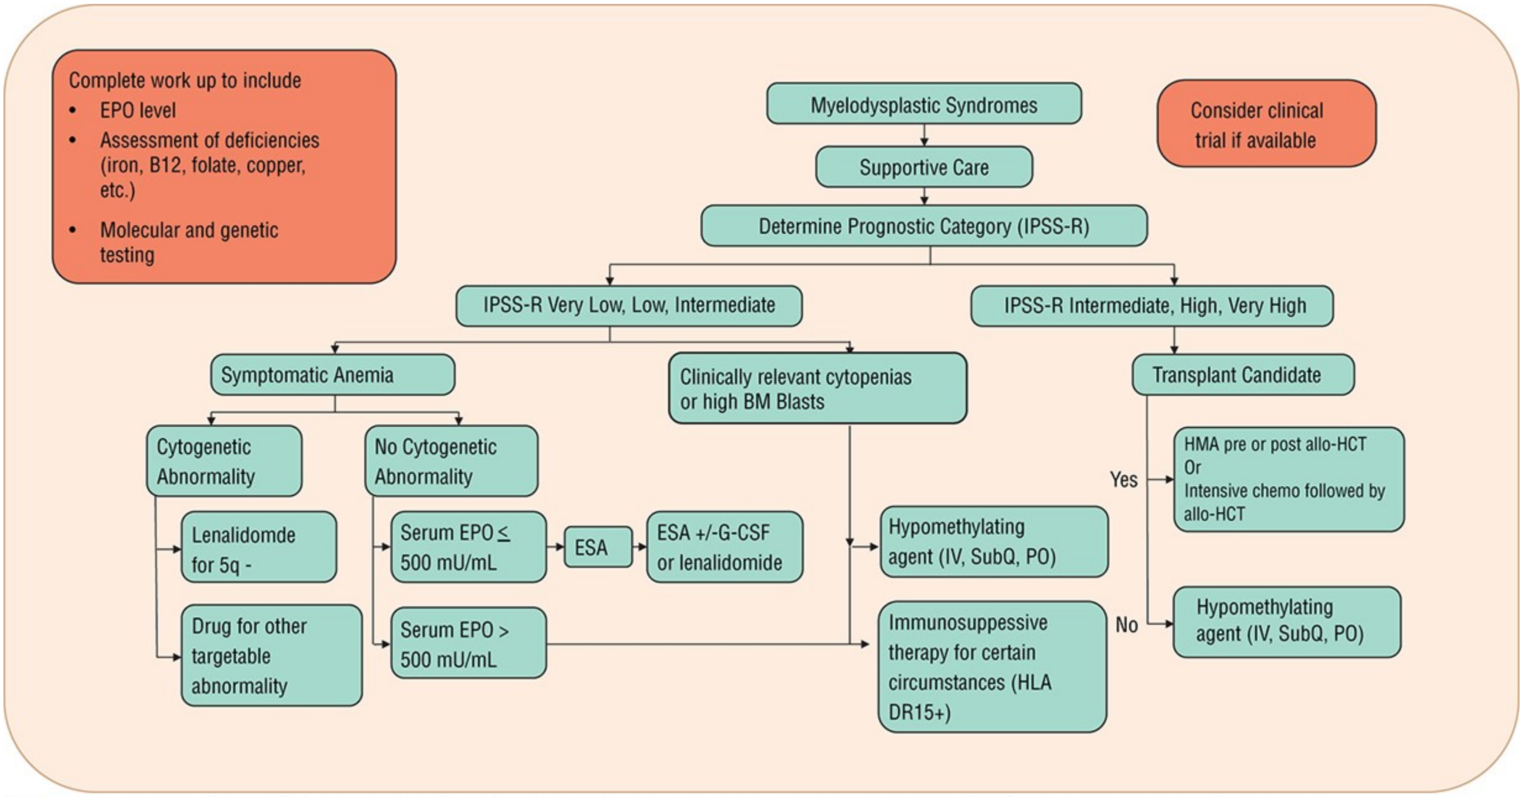
Data from Reference 34.

TREATMENT

Treatment of MDS has rapidly evolved during the past two decades following discoveries in disease biology, new research that predicts the natural history of the disease and response to a given therapy, and new treatment strategies such as molecularly guided therapy and lenalidomide (see Fig. e160-1).[2]

FIGURE e160-1

Myelodysplastic syndrome treatment algorithm. (HMA, hypomethylating agent; HCT, hematopoietic cell transplant.)



Complete work up to include
• EPO level
• Assessment of deficiencies (iron, B12, folate, copper, etc.)
• Molecular and genetic testing
Myelodysplastic Syndromes
Consider clinical trial if available
Supportive Care
Determine Prognostic Category (IPSS-R)
IPSS-R Very Low, Low, Intermediate
IPSS-R Intermediate, High, Very High
Symptomatic Anemia
Clinically relevant cytopenias or high BM Blasts
Transplant Candidate
Cytogenetic Abnormality
No Cytogenetic Abnormality
Yes
HMA pre or post allo-HCT Or Intensive chemo followed by allo-HCT
Lenalidomde for 5q -
Serum EPO ≤ 500 mU/mL
ESA
ESA +/-G-CSF or lenalidomide
Hypomethylating agent (IV, SubQ, PO)
Drug for other targetable abnormality
Serum EPO > 500 mU/mL
Immunosuppressive therapy for certain circumstances (HLA DR15+)
No
Hypomethylating agent (IV, SubQ, PO)

Treatment of MDS uses a risk-adapted approach that considers disease- and host-related factors. Patients are classified as lower-risk or higher-risk based on a prognostic system, such as the IPSS-R. In addition, host factors should be considered. Clinicians should recognize that the clinical course of MDS is not stable. The MDS may progress and patient comorbidities or symptoms may change; either of these changes may necessitate a change in treatment strategy. In general, therapy for MDS is palliative and the only curative treatment available is allogeneic HSCT. Enrollment in a suitable clinical trial is always a viable approach.

⑥ Overall goals of therapy for MDS are to (1) change the natural history of the disease (ie, delay disease progression), (2) reduce the number of RBC transfusions, and (3) improve quality of life.[34] These goals of treatment may vary with disease-related factors and patient factors including age, organ function, performance status, patient preference, and presence of symptoms related to myelodysplasia. When selecting treatment for MDS, the clinician should carefully consider comorbidities. Patients with extensive, life-limiting comorbidities or who are asymptomatic at diagnosis may warrant supportive care alone. Careful interpretation is necessary when comparing the results of clinical trials in MDS to determine treatment because baseline patient characteristics, prognostic scores, and response criteria vary widely. All patients with MDS should receive supportive care, including clinical monitoring, psychosocial support, and quality-of-life assessment.

Lower-Risk MDS Patients

The primary goal of therapy is hematologic improvement for lower-risk patients (IPSS low-, intermediate-1 risk; or IPSS-R very low, low, and intermediate; or WPSS very low, low, and intermediate).[2] Pharmacotherapy to treat lower-risk MDS includes immunomodulating agents, erythropoiesis-stimulating agents (ESAs) with or without growth factor support, immunosuppressive therapy, and hypomethylating agents.

Immunomodulating Agents

⑦ Lenalidomide is an analog of thalidomide and selectively suppresses del(5q) clones by inducing ubiquitination of the haplodeficient casein kinase 1A1 (CK1α), resulting in CKα1 degradation and erythroid growth arrest.[35] CKα1 is a kinase that is located on chromosome arm 5q. Cells that are haplodeficient, or deletion 5q, are more susceptible to this degradation process. Thus, lenalidomide should be considered in patients with MDS that harbors a del(5q) clone. Thalidomide and lenalidomide are immunomodulating drugs, frequently referred to as *IMiDs*. Thalidomide was discovered to possess anti-inflammatory, antiangiogenic, and antiapoptotic properties, prompting its investigation as a potential treatment for MDS. Initial response rates were encouraging, but low complete response rates and high rates of discontinuation because of intolerable adverse drug reactions have limited thalidomide's use in MDS.

Lenalidomide is structurally similar to thalidomide but offers a distinct safety profile and potentially enhanced therapeutic effects. Compared with thalidomide, lenalidomide causes less fluid retention, peripheral neuropathy, thrombosis, and constipation but more frequently induces neutropenia and thrombocytopenia. Pruritus, rash, diarrhea, and hypothyroidism have been reported with lenalidomide use but seldom require treatment discontinuation. Lenalidomide undergoes substantial renal elimination, and dose reduction in patients with renal insufficiency is recommended to decrease the likelihood of significant bone marrow suppression. Treatment-emergent thrombocytopenia and neutropenia during lenalidomide therapy are associated with response in low-risk MDS patients.[36] Careful consideration is necessary before reducing the dose or holding lenalidomide treatment in low-risk MDS patients who develop myelosuppression. Lenalidomide is a known teratogen. As such, its manufacturer has limited distribution of lenalidomide according to its FDA-approved risk evaluation and mitigation strategy (REMS).

Lenalidomide has been evaluated in several clinical trials. An uncontrolled trial of lenalidomide in 43 MDS patients reported a 56% overall response rate and 62% rate of transfusion independence. Patients with a clonal deletion of chromosome 5q had a 83% complete response rate.[37] A subsequent phase II trial of patients with 5q deletion and transfusion-dependent anemia evaluated lenalidomide 10 mg orally once daily. Cytogenetic remission was seen in 45% of patients with 67% achieving transfusion independence.[23] The median time-to-response was 4 weeks. The results of this pivotal trial led to FDA approval of lenalidomide for the treatment of low-risk MDS in patients with a 5q deletion. Nearly eight years later, long-term follow-up of patients enrolled in these phase II trials shows longer survival for those who achieved transfusion independence for at least 8 weeks as compared with nonresponders.[37]

A phase III randomized, placebo-controlled study of lenalidomide in low- and intermediate-1-risk MDS patients with a deletion 5q compared the efficacy and safety of lenalidomide 10 mg daily for 21 of 28 days or 5 mg daily with placebo in transfusion-dependent patients with a primary endpoint of transfusion independence for at least 26 consecutive weeks.[38] Transfusion independence was significantly improved in both the lenalidomide 10- and 5-mg groups, 56% and 43%, respectively, versus placebo at 6%. The lenalidomide 10-mg group showed significantly better transfusion independence for patients with baseline erythropoietin (EPO) levels greater than 500 mU/mL (U/L). Cytogenetic remission was achieved in 50% and 25% of the patients treated with lenalidomide 10 and 5 mg, respectively. Overall survival was not significantly different between groups, although this may reflect the crossover of more than 80% of placebo patients beginning at week 16. Patients with either isolated deletion 5q or a single additional cytogenetic abnormality were less likely to progress to AML at 24% and 21%, respectively, versus the 47% rate of progression observed in patients with two or more additional abnormalities. Further subgroup analyses showed that patients who achieved transfusion independence for greater than 182 days had an improvement in overall survival for lenalidomide-treated patients at either dose level.[2,34]

Lenalidomide has also been studied in a phase II trial of 214 patients with lower-risk MDS without 5q deletions. Transfusion independence was achieved in 26% of patients who received lenalidomide after a median of 4.8 weeks, and 43% had hematologic improvement by IWG criteria.[39] The response rate to lenalidomide is lower in patients with higher-risk MDS and those without a 5q deletion but the drug may still be considered for patients who do not respond to initial therapy.[34]

Lenalidomide may be used to restore or increase response to EPO.[40] A phase III trial randomized 195 patients to receive either lenalidomide + EPO or lenalidomide alone to determine if lenalidomide can restore hemoglobin response to EPO. All patients had either EPO refractory or a low probability of benefit from EPO, lower risk, non-deletion 5q MDS.[41,42] After four cycles of treatment, the major erythroid response rate was significantly higher in the combination arm than in the monotherapy arm. Major erythroid response was largely defined as transfusion independence and sustained rise in hemoglobin. The responses to the combination treatment were durable with a median duration of 23.8 months.

Lenalidomide may be associated with secondary malignancies. Evaluation of patients from two clinical trials treated with lenalidomide and who had del(5q) low- or intermediate-1-risk MDS were compared to outcomes with a registry-based cohort of untreated patients with RBC transfusion-dependent patients with del(5q) low- or intermediate-1-risk MDS. The 2-year overall survival probabilities were 89.9% in the lenalidomide cohort versus 74.4% in the untreated MDS cohort. The risk of AML progression was similar in both cohorts. The authors concluded that lenalidomide treatment does not increase the risk of AML progression, but instead provides a possible survival benefit in RBC transfusion-dependent patients with del(5q) low- or intermediate-1-risk MDS.[2,34]

About 5% of MDS exhibits mutations in isocitrate dehydrogenase (IDH1 and IDH2).[34] Oral IDH1 and IDH2 inhibitors are available for the treatment of acute leukemias, and work by decreasing intracellular levels of 2-hydroxygluterate to induce cell differentiation and decrease numbers of malignant cells.[43] Studies are ongoing to evaluate the activity of IDH1 and IDH2 inhibitors for MDS, particularly in the combination setting. Therapy selection based on specific mutations is becoming more prevalent in the treatment of all malignancies.

Growth Factors

⑧ As the goal of therapy for lower-risk MDS is hematologic improvement, treatment is based on transfusion needs. Patients without symptoms of anemia are typically observed, but further investigation is warranted if symptoms of anemia are present (ie, indicating a possible transfusion need). The serum EPO level can determine whether or not a patient is a candidate for ESAs. For example, patients with lower-risk MDS and symptomatic anemia who have a serum EPO level ≤500 mU/mL (U/L) are likely candidates for an ESA with or without growth factor support.[34]

EPO is a protein produced by the kidney in response to hypoxia that stimulates the proliferation and differentiation of erythroid cells. Anemic patients with MDS may have either a lower than expected endogenous serum EPO level relative to the degree of anemia present or an elevated EPO level. The mechanism of action of recombinant ESAs in MDS is not clear, but exogenous EPO may stimulate a normal clone of cells that is unresponsive to low endogenous levels of EPO, stimulate a dysplastic clone to differentiate that is less responsive to endogenous EPO, or induce apoptosis. An immunomodulatory effect of EPO, G-CSF, or GM-CSF has been proposed.

Unlike some solid tumors, no detrimental effects on overall survival or progression to leukemia attributed to the use of ESAs have been noted in patients with MDS.[44] Treatment with ESAs alone results in hematologic improvement and transfusion independence in low- and intermediate-1-risk patients. Two meta-analyses have evaluated the efficacy of ESAs in MDS. The first analysis, which included 2,106 patients from 59 studies reported between 1990 and 2005, found a hemoglobin response of about 30% based on the definition of hemoglobin response in the original publication.[45] A subsequent meta-analysis of studies reported from 1990 to 2006 that used International Working Group (IWG) criteria to define erythroid response (an increase in hemoglobin of 2 g/dL [20 g/L; 1.24 mmol/L] or transfusion independence). This report included 30 studies with 925 patients with MDS and found an overall erythroid response rate of 58% in patients receiving ESAs.[46] The latter report also suggests that EPO and darbepoetin can be used interchangeably for the management of MDS based on similar response rates achieved. The higher response rate compared with the previous meta-analysis likely reflects the inclusion of a higher proportion of patients most likely to respond to ESAs.

Patients with lower-risk MDS who have a serum EPO level less than 500 mU/mL (U/L) and a history of receiving fewer than 2 Units of RBC transfusions per month have the best chance of responding to ESAs.[34] The EPO doses required to achieve a response in MDS are higher than those used to treat renal causes of anemia, in the range from 40,000 to 60,000 Units subcutaneously 2 to 3 times/week. Darbepoetin doses ranging from 100 to 300 μg subcutaneously weekly or every other week have also been used for MDS management.[46] Doses should be titrated up or down, as clinically indicated, to achieve a hemoglobin level of 10 to 12 g/dL (100-120 g/L; 6.21-7.45 mmol/L).[34] Additionally, patients should receive at least 8 weeks of therapy before doses are adjusted or before patients are considered nonresponders because response to ESAs in MDS can be delayed.[34] The median response duration for ESAs in MDS is 1 to 2 years, and the ESA should be discontinued if there is no benefit or the response wanes.

Several trials report that the addition of G-CSF to ESAs improves hematologic response. A large phase III randomized controlled trial of ESAs in MDS compared EPO with or without G-CSF to best supportive care in 110 patients.[47] At 4 months, 34% of patients receiving EPO had an erythroid response by IWG 2006 criteria compared with 5.8% of patients receiving placebo. A total of 47% of patients had a major erythroid response when EPO doses were escalated or filgrastim was added. Patients with refractory anemia with ringed sideroblasts (RARS) were most likely to respond to the addition of filgrastim. No difference in overall survival or leukemic evolution was observed between patients receiving EPO compared with best supportive care after a median follow-up period of 5.8 years, but the study was not powered to determine differences in these outcomes.

A subsequent phase II study treated 99 patients with darbepoetin alfa 500 μg every 2 weeks subcutaneously for 12 weeks; nonresponders at 12 weeks continued the same darbepoetin regimen with the addition of filgrastim 300 μg twice weekly for an additional 12 weeks.[48] At 12 weeks, 48% of patients had a response according to IWG 2006 criteria, improving to 56% at 24 weeks after 40 of the nonresponders had filgrastim added to darbepoetin.

A meta-analysis of 15 published trials was performed to compare the erythroid response in patients who received EPO as a single agent with those who received EPO plus G-CSF or GM-CSF.[34,46] The overall erythroid response was 49%, 50.6%, and 64.5% for patients who received standard EPO (30,000-40,000 Units/week), standard EPO plus G-CSF or GM-CSF, or high-dose EPO (60,000-80,000 Units/week), respectively. The authors concluded that higher doses of single-agent EPO are more effective than standard doses alone or in combination with G-CSF or GM-CSF. However, a significantly higher proportion of transfusion-dependent patients were enrolled in the trials of combination therapy compared with the other two treatment groups which could have negatively impacted the outcomes.

Some, but not all, studies have shown that patients who respond to ESAs have improved quality of life. Although EPO, with or without G-CSF, does not improve overall survival, it does not shorten overall survival or time-to-development of leukemia and may decrease the need for RBC transfusions and improve quality of life. ESA therapy is well tolerated, and the National Comprehensive Cancer Network (NCCN) guideline recommends a trial in lower-risk patients who have a serum EPO level less than 500 mU/mL (U/L) and a limited transfusion history to target a hemoglobin of 10 to 12 g/dL (100-120 g/L; 6.21-7.45 mmol/L).[34]

Luspatercept is a novel erythroid maturation agent that was recently FDA-approved for anemia due to MDS with ring sideroblasts or myelodysplastic/myeloproliferative neoplasms with ring sideroblasts and thrombocytosis. This includes patients with very low to intermediate risk MDS. Luspatercept is indicated for patients who have failed ESAs and require two or more RBC transfusions over a 8-week period.[49] Luspatercept binds to endogenous transforming growth factor-beta (TGF-β) ligands, which reduces SMAD2 and SMAD3 signaling, and ultimately increases differentiation and proliferation of RBC precursors. In the MEDALIST phase III, double-blind, randomized trial, patients received either luspatercept subcutaneously every 3 weeks or placebo. Dosing of this agent started at 1 mg/kg subcutaneously every 3 weeks for two doses, and if minimal response, the dose can be increased every two cycles (6 weeks) to a maximum dose of 1.75 mg/kg. Transfusion independence was achieved in 38% of the study group versus 13% in the placebo group. The drug was generally well tolerated, with fatigue, diarrhea, asthenia, nausea, and dizziness most commonly reported. The incidence of adverse drug reactions decreased over time.[49]

Thrombopoietin is a hormone synthesized in the liver and secreted into the systemic circulation, where it binds to thrombopoietin receptors on stem cells, progenitor cells, and platelets, resulting in increased platelet production. Romiplostim and eltrombopag are novel drugs that stimulate the thrombopoietin receptor similar to endogenous thrombopoietin. Both agents are FDA approved for patients with chronic idiopathic thrombocytopenic purpura and eltrombopag is also indicated for use in chronic hepatitis C–associated thrombocytopenia and severe aplastic anemia.

A randomized, placebo-controlled trial of romiplostim to manage thrombocytopenia in MDS was stopped early in 2011 because of safety concerns regarding the potential for transient increases in blast cell counts and the risk for progression to AML; 6% of romiplostim patients developed progression to AML compared with 2.4% of placebo patients.[50] A warning about the risk for progression from MDS to AML, potential for an increase in blast percentage without progression to AML, and a limitation of use noting romiplostim is not indicated for use in MDS were subsequently included in the romiplostim label. Only 56 of a planned 250 patients completed the 58-week study; longer follow-up shows no difference in the risk for progression to AML or overall survival. The study design limits the ability to detect a true risk for progression to AML to romiplostim.

A multicenter phase I/II trial evaluated the safety and tolerability of eltrombopag for the treatment of thrombocytopenia in adult patients with advanced MDS, sAML, or *de novo* AML.[51] Patients were randomized to once daily eltrombopag or placebo. In total, 98 patients participated in the study. Drug-related adverse drug reactions of grade 3 or higher were reported in 9% of participants in the eltrombopag arm versus 12% in the placebo arm. Increases in the percentage of peripheral blasts did not differ significantly between groups. The NCCN guidelines recommend a TPO agent only in MDS patients with severe thrombocytopenia.[34] Further studies of TPO agents investigating the risk of progression to AML and the benefit in patients with MDS are warranted.

Immunosuppressive Therapy

⑨ A subset of lower-risk MDS patients respond well to immunosuppressive agents. Immunosuppressive agents that modulate effector T-cells, including antithymocyte globulin (ATG), cyclosporine, and corticosteroids have been evaluated in patients who have hypoplastic MDS with a disease pathobiology similar to aplastic anemia. The National Institutes of Health has developed an algorithm to predict response to immunosuppressive therapy based on age younger than 60 years, hypocellular marrow, refractory anemia of short duration, trisomy 8 as the sole cytogenetic abnormality, and HLA DR15 positive expression.[31] ATG, with or without cyclosporine, has been investigated primarily in patients with intermediate-1-risk and low-risk MDS. Treatment with ATG may not be beneficial for all patients because of the potential for infectious complications and serum sickness. Most studies have used equine ATG at a dose of 40 mg/kg/day IV for 4 consecutive days with corticosteroids to prevent serum sickness complications.[31,52] A retrospective evaluation of patients enrolled in clinical trials at the National Institutes of Health demonstrated that the combination of equine ATG and cyclosporine was associated with response to therapy compared with either agent administered alone.[53] Responses generally occur within 4 months, and about one-third of previously transfusion-dependent patients achieve durable transfusion independence.[31,52] Rabbit ATG has also been evaluated in daily doses ranging from 2.5 to 3.75 mg/kg/day administered IV for 4 to 5 consecutive days.[54–56] Response rates are similar and treatment with either horse or rabbit ATG is reasonable.

A survival benefit from therapy with ATG has not been demonstrated, despite clinical trials of various regimens including both formulations plus cyclosporine or corticosteroids, with or without hematopoietic growth factor support. A phase III randomized controlled trial compared equine ATG and cyclosporine versus best supportive care in all IPSS risk categories.[57] At 6 months, 29% of patients achieved a hematologic response in the immunosuppressive therapy arm compared with 9% of those receiving best supportive care, but no difference was seen in overall, leukemia-free, or 2-year transformation-free survival. Notably, these patients were not evaluated for HLA DR15, and nearly 25% of patients in each group had undetermined risk, intermediate-2-risk, or high-risk IPSS.

Hypomethylating Agents (HMA)

Azacitidine and decitabine are nucleoside analogs structurally similar to cytosine and capable of being incorporated into DNA in place of cytosine. When these agents incorporate into DNA, substitution of carbon for nitrogen at the 5′ position prevents methylation by DNA methyltransferase. As a result, DNA methylation is decreased, and genes previously silenced by aberrant hypermethylation are activated. In vitro studies have confirmed that these agents can promote the reexpression of previously silenced genes.[24] The activity of both agents is concentration and time dependent, and trials are ongoing to evaluate the optimal dose, route, schedule, and duration of therapy.

The median time-to-response with DNA hypomethylating agents is 3 to 4 months.[2] Long-term follow-up of high-risk MDS patients who responded to azacitidine therapy reported the median time-to-first response was two cycles, and 91% of responding patients achieved their first response within six cycles. The first response was the best response in 52% of patients; the remaining 48% did not achieve their best response until a median of three additional cycles beyond their first response.[34] Experts recommend continuing therapy until evidence of disease progression or unacceptable toxicity even in patients who only achieve stable disease.[2,34]

The primary dose-limiting toxicity of both azacitidine and decitabine is myelosuppression, including leukopenia, granulocytopenia, and thrombocytopenia. Febrile neutropenia and other infectious complications have been reported with azacitidine and decitabine.[58,59] Nausea and vomiting may occur and antiemetic prophylaxis is recommended. Azacitidine-induced erythema at the site of subcutaneous injection may occur and can be minimized with the use of cold compresses. Rare hepatotoxicity is reported after either azacitidine or decitabine. Hypomethylating agents should be used cautiously in patients with an estimated glomerular filtration rate of less than or equal to 29 mL/min/1.73 m^2. Pharmacokinetics of a single cycle in this population do not demonstrate significant variability in area-under-the-curve or maximum observed plasma concentration, but cumulative dosing may increase the risk of grade 3 or 4 myelosuppression, necessitating cycle delays and dose reductions.

It remains unclear if the degree of DNA methylation at baseline or the level of demethylation response predicts success and survival after treatment. Higher levels of methylation correlate with shorter median overall survival and progression-free survival. The degree of methylation at baseline did not predict response to decitabine. Mutations in *TET2* likely affect the global methylation level, but changes in methylation status as a result of treatment have not yet been evaluated.[60] Methylation levels are not routinely incorporated into clinical decision making for MDS therapy at this time.

Azacitidine activity in MDS has been evaluated in a phase III, multicenter, randomized trial of patients with any classification of MDS based on FAB criteria.[59] Patients in lower-risk categories of MDS, including refractory anemia and RARS, were required to meet additional criteria for significant bone marrow dysfunction. A total of 191 patients were randomized to treatment with either supportive care alone or supportive care plus azacitidine 75 mg/m^2 subcutaneously once daily for 7 days, repeated every 28 days. Hematopoietic growth factor support was not permitted. Responses based on Cancer and Leukemia Group B criteria occurred in 60% of patients in the azacitidine group compared with 5% in the supportive care alone group. Almost half of the patients previously transfusion dependent who received azacitidine became transfusion independent. Although the rate of progression to AML was significantly lower with azacitidine compared with supportive care alone, azacitidine did not significantly improve overall survival. A quality-of-life analysis identified a significant advantage for azacitidine therapy compared with supportive care alone, including improvements in physical functioning, fatigue, dyspnea, psychosocial distress, and affect.[61]

Decitabine was also evaluated in a multicenter, randomized phase III trial of patients diagnosed with MDS by FAB criteria.[58] Patients were required to have an IPSS risk of intermediate-1 or greater and two-thirds of patients had intermediate-2- or high-risk MDS. A total of 170 patients were randomized to either supportive care alone or supportive care plus treatment with decitabine 15 mg/m^2 by IV infusion every 8 hours for 3 days repeated every 6 weeks. In contrast to the azacitidine trial, hematopoietic growth factor support was allowed. The overall response rate by IWG criteria was 17% in the decitabine group compared with 0% in the supportive care group. Thirteen percent of patients who received decitabine experienced hematologic improvement compared with 7% who received supportive care alone. Time-to-progression to AML or overall survival was not significantly different between groups. The patients with known clonal abnormalities at baseline who underwent follow-up cytogenetic evaluation were noted to have a complete cytogenetic response of 35% with decitabine compared with 10% in the supportive care arm. Decitabine also improved quality-of-life measures, including global health status, fatigue, and dyspnea.

Azacitidine dosing strategies have been evaluated in a trial of 151 lower-risk MDS patients.[62] Patients were randomized to receive azacitidine 5-2-2 (75 mg/m^2/day subcutaneously for 5 days followed by 2 days of rest [to account for a weekend] followed by azacitidine 75 mg/m^2/day subcutaneously for 2 more days) versus azacitidine 5-2-5 (50 mg/m^2/day subcutaneously for 5 days followed by 2 days of rest [to account for a weekend] followed by azacitidine 50 mg/m^2/day subcutaneously for 5 more days) versus azacytidine 5 (75 mg/m^2/day subcutaneously for 5 days); all strategies were administered every 4 weeks for six cycles. Hematologic improvement was noted in 44%, 45%, and 56%, respectively. Further, RBC transfusion independence was observed in 50%, 55%, and 64%, respectively. The authors concluded that all three dosing strategies for azacitidine had similar outcomes to standard FDA-approved dosing.

To understand dosing strategies in low-risk MDS further, one study evaluated low-dose azacitidine versus low-dose decitabine.[63] In that study, azacitidine 75 mg/m^2 was administered intravenously or subcutaneously every 24 hours for 3 days. Decitabine 20 mg/m^2 was administered IV every 24 hours for 3 days. Cycles for each agent were every 28 days. Overall response and cytogenetic response rates were higher for decitabine as compared with azacitidine. No significant difference in event-free survival was observed.

Higher-Risk MDS Patients

The primary goal of pharmacotherapy in higher-risk MDS is to change the natural history of MDS. DNA hypomethylating agents may prolong overall survival, but allogeneic HSCT remains the only curative option for patients. Because most patients with MDS are not candidates for HSCT, less-toxic therapeutic modalities are being evaluated to improve quality of life and disease-free survival.

Immunomodulating Agents

The activity of lenalidomide in low-risk MDS patients prompted its evaluation in patients with higher-risk MDS with 5q deletion. A phase II trial of lenalidomide in patients with higher-risk MDS with a 5q deletion and other cytogenetic abnormalities reported responses by IWG 2006 criteria in 27% of patients. Significant myelosuppression was reported and most patients required hospitalization.[64] Patients with thrombocytopenia or additional cytogenetic complexity progressed rapidly despite lenalidomide therapy.

Hypomethylating Agents

Azacitidine has been evaluated in patients with higher-risk MDS. In a randomized controlled trial of 191 patients with MDS, azacitidine 75 mg/m^2/day subcutaneously for 7 days in 28 day cycles was compared to supportive care. The median time-to-leukemic transformation or death was 21 months for azacitidine versus 13 months for supportive care. Transformation to AML occurred as the first event in 15% of those receiving azacitidine compared with 38% receiving supportive care.[59] Data analysis, which removed the cross-over effect of the trial, determined an additional 18 months for azacitidine versus 11 months for supportive care. A subsequent analysis combined the results of three clinical trials of azacitidine in MDS and used WHO diagnostic criteria and IPSS prognostication.[65] These trials tested azacitidine 75 mg/m^2/day administered either intravenously or subcutaneously daily every 28 days. The overall response was 60%. The median number of cycles to first response was three and 90% of responses were observed by cycle 6. Azacitidine did not increase the risk of infection or bleeding.

An open-label, randomized, phase III study compared azacitidine with a conventional care regimen in patients with higher-risk MDS.[2,34] Before randomization, treating physicians selected supportive care alone, low-dose cytarabine, or AML-type induction as the conventional care regimen for a given patient if randomized to the conventional care arm. Of the 340 patients receiving treatment, 175 received azacitidine, 102 received best supportive care, 44 received low-dose cytarabine, and 19 received AML-type induction. At 2 years, 51% of azacitidine patients were alive compared with 26% of patients who received a conventional care regimen, and median overall survival was prolonged by 9 months. This is the only randomized controlled study to demonstrate that therapy improves overall survival in MDS.

In an attempt to better define which patients are most likely to respond to azacitidine, Itzykson and colleagues identified four factors that independently predicted overall survival in a cohort of 282 higher-risk MDS patients who received azacitidine for a median of six cycles in a compassionate use study.[2,34] Each factor was assigned a score: performance status greater than or equal to 2 (1 point), intermediate- and poor-risk cytogenetics (1 and 2 points, respectively), presence of circulating blasts (1 point), and RBC transfusion dependency of at least 4 Units within 8 weeks (1 point). Median overall survival was not reached in the low-risk (0 point), 15 months in intermediate-risk (1-3 points), and 6.1 months in high-risk (4-5 points) patients. This prognostic scoring system was independently validated in the azacitidine cohort of another study.

Decitabine has also been compared with best supportive care in a phase III trial of 233 intermediate- or high-risk MDS patients older than 60 years who were ineligible for intensive chemotherapy.[66] Decitabine was more active than best supportive care, with a complete and partial response rate of 13% and 6%, respectively, versus 0% for best supportive care. Median progression-free survival was significantly improved with decitabine compared with supportive care at 6.6 months versus 3 months, respectively. Progression to AML at 1 year was significantly reduced with decitabine to 22% versus 33% in the best supportive care arm. However, unlike the trial with azacitidine, no overall survival benefit was observed. Decitabine did improve quality-of-life measures of fatigue and physical functioning. Another phase III trial evaluated decitabine versus best supportive care and demonstrated a response rate of 17% versus 0%, but this trial used decitabine 15 mg/m^2/day intravenously every 8 hours for 3 days as part of 6-week cycles.[58] This dose differs from the FDA-approved dose.

These pivotal trials for azacitidine and decitabine led to the approval of both agents for the treatment of patients with MDS. However, the FDA-approved administration schedules for decitabine were inconvenient for many cancer centers whose outpatient clinics were not open extended hours or on weekends, necessitating hospitalizations. A more convenient regimen for decitabine (20 mg/m^2 by intravenous infusion daily for 5 consecutive days every 4 weeks) demonstrated similar response rates and adverse events to the traditional regimen.[67] In early 2010, the FDA granted approval for this alternative dosing regimen.

Oral decitabine with cedazuridine was FDA approved for use in MDS in July 2020. Hypomethylating agents, specifically decitabine and azacitidine, are rapidly inactivated by cytidine deaminase in the gastrointestinal tract when given orally. Cedazuridine inhibits cytidine deaminase and allows for increased decitabine exposure with the oral route.[68] In a phase II cross-over trial, the oral formulation of decitabine 35 mg with cedazuridine 100 mg daily for 5 days was compared with standard-dose decitabine 20 mg/m^2 intravenously daily for 5 days each of a 28-day cycle (note the flat-dose of the oral formulation, rather than BSA or weight-based dosing). Patients had intermediate 1 or 2, or high-risk MDS by the IPSS. This trial demonstrated similar pharmacokinetic and pharmacodynamic outcomes with the oral and intravenous approaches. Clinical responses were observed in 60% of the 80 study patients, including a complete response rate of 21%. Cedazuridine/decitabine tablets should not be taken within 2 hours before or after food, and premedication with an antiemetic is recommended.[69] The current NCCN guidelines list oral decitabine and cedazuridine as a substitute for intravenous decitabine, regardless of MDS prognostic category.[34]

Despite some activity with both hypomethylating agents used separately, sequencing decitabine after azacitidine failure is not effective. A retrospective study evaluated 25 MDS and AML patients with disease progression or lack of response to azacitidine who went on to receive decitabine.[2,34] Five patients demonstrated stable disease with decitabine but no patient achieved a response. Thus, higher-risk MDS patients who fail hypomethylating therapy may require an alternative therapeutic intervention with a different mechanism of action or participate in a clinical trial.

Preliminary results of an oral azacitidine formulation given for 14 or 21 days have been published. The extended dosing strategy results in sustained demethylation throughout the entire treatment cycle. An ongoing phase III trial of oral azacytidine in lower-risk MDS with significant cytopenias should provide more definitive information on its place in therapy.[70]

Another strategy for patients with treatment-naïve high-risk MDS is the combination of azacitadine and venetoclax. Venetoclax is an oral B-cell lymphoma (BCL-2) inhibitor.[71] BCL-2 is an anti-apoptotic protein that mediates tumor cell survival and is overexpressed in several hematologic malignancies. Although new to the MDS landscape, venetoclax has demonstrated activity in chronic lymphocytic leukemia, acute leukemias, and lymphomas. An ongoing open-label, phase Ib trial provided venetoclax at escalating doses for 14 days and azacitidine 75 mg/m^2/day administered subcutaneously or intravenously days 1 through 7 of each 28-day cycle to patients with high-risk MDS. The overall response rate was 77%, with 42% complete responses. Median duration of response was 14.8 months and progression-free survival was 17.5 months in the 57 patients treated. The incidence of toxicities was high with >grade 3 events in nearly all patients, specifically neutropenia, febrile neutropenia, and thrombocytopenia. These early results compare favorably to single-agent hypomethylating agents, although the combination has not been compared to the standard of care.

⑩ The lack of a durable survival benefit with existing therapies and the inability to offer HSCT in many patients has led to clinical trials of combination therapy with hypomethylating agents. A phase II/III trial randomized patients with higher-risk MDS and CMML to azacitidine alone, azacitidine plus lenalidomide, and azacitidine plus vorinostat.[72] In this study of 277 patients, the overall response rate was similar (38%, 49%, and 27% for azacitidine, azacitidine plus lenalidomide, and azacitidine plus vorinostat, respectively). The risk of serious adverse events was similar, but patients receiving azacitidine and another drug were more likely to require protocol-based dose modifications. Interestingly, mutations in DNMT3A were associated with a higher overall response rate while SRSF2 mutations were associated with a lower overall response rate. Patients with fewer mutations had a longer duration of response. Further evaluation is required to determine the optimal hypomethylating agent treatment regimen and therapeutic options in higher-risk MDS after hypomethylating agent resistance develops.

Intensive Chemotherapy

Patients with higher-risk MDS may be candidates for intensive chemotherapy with AML-type induction combination chemotherapy regimens. AML-induction combination therapy includes anthracyclines and cytarabine and is described in detail in Chapter 157. This type of intensive chemotherapy in MDS patients is often less successful than *de novo* AML, with complete remission rates of 40% to 60%, a median duration of response of only 10 to 12 months, and a longer period of aplasia.[34] Treatment-related mortality in younger patients with current supportive care measures, including antibiotic and hematopoietic growth factor support, is less than 10%.[2] Patients younger than 55 years who have a favorable karyotype and good performance status are most likely to benefit, but this approach cures fewer than 15% of patients. Intensive chemotherapy can be used as a bridge to allogeneic HSCT to reduce tumor burden and control disease while a suitable donor is found and a referral is made to a transplant center.

Hematopoietic Stem Cell Transplantation

⑪ Allogeneic HSCT offers potentially curative therapy to patients with MDS who have a suitable donor and are healthy enough for the procedure. With a median age of 76 years at the time of diagnosis, fewer than 5% of MDS patients are referred for allogeneic HSCT.[2,34] Two large retrospective studies indicate that recipient age alone should not be a contraindication to allogeneic HSCT.[73,74] About 30% to 50% of patients with MDS treated with allogeneic HSCT have prolonged disease-free survival.[73] However, 20% to 50% of patients succumb to treatment-related mortality, and many of the remaining patients experience relapse. Outcomes vary based on patient comorbidities, time from diagnosis to transplant, MDS subtype, percentage of bone marrow blasts at the time of HSCT, IPSS risk category, type of conditioning regimen administered before HSCT, and dose and source of stem cells infused.[73] Complications of allogeneic HSCT are described in greater detail in Chapter e163. An HLA-matched allogeneic HSCT is recommended if an appropriate donor is available. An autologous HSCT can be considered in the context of a clinical trial if an allogeneic donor is not available, complete remission is achieved with chemotherapy, and adequate stem cells can be collected.

Because of the high rate of treatment-related mortality in patients with MDS, allogeneic HSCT is not recommended for lower-risk MDS patients because these patients may have stable disease for several years, and early transplant may shorten overall survival. The International MDS Risk Assessment Workshop conducted a decision analysis based on clinical data from two international registries and a single center to identify the optimal time to recommend allogeneic HSCT for patients who have a donor and meet HSCT eligibility criteria.[2,34] The analysis showed that patients with low- and intermediate-1 IPSS risk scores should be closely observed and transplanted at the time of disease progression. Patients with intermediate-2 and high IPSS risk scores should be transplanted soon after diagnosis to confer the greatest benefit from allogeneic HSCT. This model was developed in 2003 and included patients younger than 60 years who had undergone HSCT primarily in the 1990s. It did not incorporate treatment with novel agents for MDS, the use of reduced-intensity conditioning (RIC), or all of the known prognostic factors available and thus may not apply to contemporary patients being evaluated for HSCT.

The WPSS may enhance the selection of patients likely to derive the most benefit from allogeneic HSCT. Based on recent retrospective data, patients with lower-risk disease have low rates of treatment-related mortality and relapse, and a 5-year overall survival rate of 80%.[75] Another retrospective series reported a 4-year overall survival rate of 52% in younger patients with lower-risk refractory anemia after allogeneic HSCT, remarkably similar to the median survival rate for untreated patients with refractory anemia.[2,34] The decision to proceed to allogeneic HSCT and optimal timing should be weighed carefully at diagnosis and subsequently at regular intervals for factors that might influence prognosis, such as degree of cytopenias, cytogenetic abnormalities, transfusion requirement, progression to a higher-risk category, donor availability, comorbidities, and availability of effective nontransplant therapies. Prospective studies comparing allogeneic HSCT with hypomethylating agents or best supportive care are ongoing.

It is difficult to compare the results from patients receiving RIC with myeloablative conditioning regimens because patients treated with RIC regimens tend to be older or have significant comorbid illnesses preventing them from receiving myeloablative conditioning regimens. However, a recent phase III prospective open-label randomized trial compared a busulfan-based RIC with myeloablative conditioning in patients with MDS or sAML.[76] Patients were stratified by donor, age, and blast count. The rate of engraftment and risk of acute and chronic graft-versus-host disease were comparable between both groups. Two-year relapse-free survival and overall survival were similar in the two groups. The selection of the conditioning regimen for HSCT in MDS patients should continue to be patient specific. The only curative therapy for MDS patients is allogeneic HSCT, but most patients lack a suitable donor, are not healthy enough to undergo this intensive therapy, or may not be referred for HSCT because of advanced biologic age despite adequate health and organ function.

Supportive Care

All patients with MDS should receive appropriate supportive care and be encouraged to participate in clinical trials to determine the role of different approaches in the management of MDS.[34] The NCCN guidelines recommend that patients with symptomatic anemia should receive leukoreduced RBC transfusions, and those with bleeding caused by thrombocytopenia or platelet counts below 10,000 cells/mm^3 (10×10^9/L) should receive platelet transfusions.[34] Hematopoietic growth factor support should be considered in patients with refractory, symptomatic cytopenias. Patients with evidence of infection should have an appropriate diagnostic evaluation based on history and physical examination followed by appropriate antimicrobial therapy. Routine antimicrobial or hematopoietic growth factor prophylaxis is not recommended in the absence of repeated infections. Iron chelation may be considered in lower-risk patients and candidates for allogeneic HSCT who have received more than 20 to 30 RBC transfusions in their lifetime and are expected to continue to require transfusions.[34]

Infection

Patients with MDS may be neutropenic or have functional defects in neutrophils, predisposing them to infection.[21] In MDS, the most frequently isolated organisms are bacteria, and the most common sites of infection are the lungs, urinary tract, and bloodstream. Patients with evidence of infection should have appropriate diagnostic evaluation based on history and physical examination and then appropriate antimicrobial therapy. Neutropenic patients with evidence of infection or fever of unknown origin should receive empiric broad-spectrum, intravenous antibiotics.

Hematopoietic Growth Factors

Filgrastim (G-CSF) and sargramostim (granulocyte-macrophage colony-stimulating factor [GM-CSF]) are colony-stimulating factors that stimulate white blood cell production and may increase circulating neutrophils in 70% to 90% of patients, which may decrease the risk of infection.[77] These agents are not beneficial as chronic monotherapy because they do not reliably prevent infection and have no impact on survival. Filgrastim, sargramostim, or any biosimilar product should only be administered temporarily as monotherapy in the rare neutropenic MDS patient who develops recurrent severe infections. Pegfilgrastim, a long-acting myeloid growth factor, does not have a place in MDS treatment.[34]

Transfusions

Patients generally receive RBC transfusions when they develop signs or symptoms of anemia, including tachycardia, fatigue, or dyspnea, which generally occur when hemoglobin drops below 8 to 10 g/dL (80-100 g/L; 4.97-6.21 mmol/L).[34] Some clinicians use a transfusion threshold of 10 g/dL (100 g/L; 6.21 mmol/L) in patients with significant cardiovascular disease. Platelet transfusions are generally reserved for patients with evidence of bleeding to avoid alloimmunization from repeated platelet transfusions, which leads to refractoriness to donor platelets.

Iron Overload

RBC transfusions are associated with shortened leukemia-free and overall survival times in MDS.[2] It is unclear if this reflects disease severity or is a direct result of iron toxicity. MDS patients receiving RBC transfusions are at higher risk for infections, cardiac, hepatic, and endocrine dysfunction compared with nontransfused MDS patients or the general population without MDS.[78] The role of excess iron is unclear as anemia likely contributes to heart failure and neutropenia to infections.

Prospective clinical trials in MDS demonstrate that iron chelation is able to decrease markers of iron overload.[79–82] Six studies of over 700 patients with MDS receiving deferasirox for iron overload show improvement in hematologic parameters related to chelation with an increase in hemoglobin level ranging from 6% to 45%, an increase in platelet count from 13% to 61%, and in neutrophil count from 3% to 76%.[83] Eight observational studies have assessed the relationship between iron chelation and overall survival in about 1,500 patients with low-risk and intermediate-1-risk patients with MDS. A meta-analysis reported an improvement in overall survival of 61.2 months, with seven of eight studies reporting improvement in overall survival.[83] It is possible that patients who had a better prognosis were more likely to receive iron chelation, which would explain the association between improved survival time and iron chelation. In a cohort of Medicare beneficiaries with MDS, a longer duration of deferasirox use correlated with improved overall survival times, but deferasirox use was not associated with the risk of heart failure or endocrine or renal disease.[2,34] It is hypothesized that iron chelation may lower infection risk, improve the outcome of allogeneic HSCT, and delay leukemic transformation in patients with MDS. A randomized controlled trial comparing deferasirox with placebo in low- and intermediate-1-risk MDS patients with transfusional iron overload with a primary outcome of event-free survival is ongoing.

The potential toxicity, expense, and benefits of iron chelation should be carefully considered before initiating therapy. Deferasirox and deferoxamine are FDA approved for use in patients with chronic iron overload caused by RBC transfusions. Deferiprone is FDA approved for patients with transfusional iron overload secondary to thalassemia when current chelation therapy is inadequate. The prescribing information for deferiprone has a black box warning regarding agranulocytosis, which may lead to serious infection and death. The prescribing information for deferasirox has a black box warning describing renal and hepatic impairment and GI hemorrhage; fatalities were reported. These reactions were more frequently observed in patients with advanced age, high-risk MDS, underlying renal or hepatic impairment, or thrombocytopenia (less than 50,000 cells/mm^3 [50 × 10^9/L]). Diarrhea may complicate therapy with deferasirox and recommendations for management have been published.

The NCCN guidelines recommend that iron chelation be initiated when greater than 20 RBC transfusions are administered or when serum ferritin levels exceed 2,500 ng/mL (μg/L; 5,620 pmol/L) in patients with lower-risk MDS who have an anticipated survival of at least 1 year or in patients proceeding to allogeneic HSCT.[34] For patients who start on iron chelation therapy due to an elevated ferritin, it is recommended to continue therapy until the ferritin level is <1,000 ng/mL [μg/L; 2,250 pmol/L]).[34] Patients receiving pharmacotherapy for iron chelation should be monitored for gastrointestinal and ocular toxicity, ototoxicity, renal and hepatic dysfunction, and complete blood counts in addition to markers of iron overload.

EVALUATION OF THERAPEUTIC OUTCOMES

Standardized response criteria in clinical trials of MDS enable clinicians to evaluate study outcomes, compare results from different trials, and tailor therapy according to patient or disease characteristics. The IWG for MDS guidelines for response criteria in MDS clinical trials categorize patient responses into categories that correlate with quality of life or morbidity.[2,34] Based on these criteria, the four treatment goals are to change the natural history of the disease, cytogenetic response, hematologic improvement, and improve quality of life. Changes in the WHO classification system and new therapies with novel mechanisms of action, time to response, and likelihood of treatment-related cytopenias have created a need for further refinement of these guidelines. Patients with MDS should have regular follow-up with a history, physical examination, and complete blood counts. The frequency of follow-up varies with the natural history of each patient from weekly to every 6 months.

CONCLUSION

MDS are a heterogeneous group of myeloid stem cell disorders, ranging widely in prognosis and type of treatment. A prognostic scoring system, IPSS-R, can be applied at the time of diagnosis to predict disease progression and treatment selection. Low-risk MDS treatments use monitoring, growth-factor support, hypomethylating agents, and other agents to improve cytopenias. Intermediate- and high-risk MDS have a higher risk of progressing to more aggressive forms, such as AML. Consequently, more aggressive treatment strategies can be considered in younger and more fit patients. Supportive care strategies must be considered in the optimal treatment of the patient with MDS. The need for blood transfusions is common in advanced or end-stage MDS, with the associated risk of iron overload secondary to the transfusions. Patients with MDS are at higher for infections from the disease or its treatment and infections must be treated promptly.

Treatments for MDS are evolving and incorporate more targeted therapies, including lenalidomide, BCL-2 inhibitors, and IDH mutation-directed therapies. Careful consideration of disease- and patient-specific characteristics will lead to more personalized therapies and optimal outcomes.

ABBREVIATIONS

AML	acute myeloid leukemia
sAML	secondary acute myeloid leukemia
ASXL1	additional sex combs like-1
ATG	antithymocyte globulin
CBC	complete blood count
DNA	deoxyribonucleic acid
DNMT3A	DNA-methyltransferase 3A
EPO	erythropoietin or epoetin alfa
ESA	erythropoiesis-stimulating agent
EZH2	enhancer of zest homolog 2
FAB	French-American-British

FDA	Food and Drug Administration
GATA2	GATA binding protein 2
G-CSF	granulocyte colony-stimulating factor
GM-CSF	granulocyte-macrophage colony-stimulating factor
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HMA	hypomethylating agent
HSCT	hematopoietic stem cell transplantation
IMiD	immunomodulating drug
IPSS	International Prognostic Scoring System
IPSS-R	International Prognostic Scoring System—Revised
IWG	International Working Group
KRAS	Kirsten rat sarcoma gene
LDH	lactate dehydrogenase
MAPK	mitogen-activated protein kinase
MDS	myelodysplastic syndromes
MECOM	MDS1 and EV11 complex locus protein
MLL	mixed lineage leukemia gene
NCCN	National Comprehensive Cancer Network
NF1	neurofibromatosis type 1 gene
NRAS	neuroblastoma rat sarcoma gene
PRBC	packed red blood cells
PTPN11	protein tyrosine phosphatase non-receptor type 11
RARS	refractory anemia with ringed sideroblasts
RIC	reduced-intensity conditioning
RBC	red blood cell
RNA	ribonucleic acid
mRNA	messenger ribonucleic acid
RUNX1	runt-related transcription factor 1 gene
SF3B1	splicing factor 3B subunit 1
SRSF2	serine and arginine rich splicing factor 2
STAG2	stromal antigen 2 gene

TET2	tet methylcytosine dioxygenase 2
TIBC	total iron binding capacity
t-AML	therapy-related AML
t-MDS	therapy-related MDS
TP53	tumor suppressor protein 53
TPO	thrombopoietin
TR-MN	therapy-related myeloid neoplasm
TSH	thyroid stimulating hormone
U2AF1	U2 small nuclear RNA auxiliary factor 1
WHO	World Health Organization
WPSS	World Health Organization Classification-based Sc oring System
ZRSR2	zinc finger RNA binding motif serine/arginine risk 2 gene

SELF-ASSESSMENT QUESTIONS

1. Which of the following descriptions has the highest risk for developing MDS based on host characteristics?

   A. An 88-year-old man with a history of non-Hodgkin lymphoma treated with chemotherapy plus radiation

   B. A 21-year-old man with no significant past medical history

   C. A 45-year-old woman with a history of rheumatoid arthritis

   D. A 7-month-old infant

2. What is the dose-limiting toxicity of azacytidine and decitabine?

   A. Nausea and vomiting

   B. Mucositis

   C. Myelosuppression

   D. Hepatotoxicity

3. Significant opportunity exists for pharmacists to play a large role in the treatment of MDS patients. Given the median age of diagnosis for MDS, which medication-related problem is most likely to be indicated for resolution while providing pharmacist care services?

   A. Breast feeding contraindications

   B. Pregnancy considerations

   C. Immunization status

   D. Polypharmacy

4. Lenalidomide is associated with a risk evaluation and mitigation strategy (REMS). Why does lenalidomide have a REMS program in place?

   A. Complex manufacturing processes

   B. Oral chemotherapy

   C. Teratogenic

   D. Manufactured outside of the United States

5. JV is a 68-year-old male with lower-risk MDS who is being treated with lenalidomide. Unfortunately, JV contracted a gastrointestinal illness associated with significant emesis. JV became dehydrated and went to the emergency room. At the emergency room, his serum creatinine was noted to be elevated to 2.5 mg/dL (221 μmol/L). Which of the following is the most appropriate recommendation at this time?

   A. Maintenance intravenous fluids

   B. Hold lenalidomide

C. Ondansetron

D. Levofloxacin

6. Lenalidomide is targeted therapy that is most appropriate for which of the following bone marrow results?

A. Del(5q)

B. Normal cytogenetics

C. TP53

D. Complex cytogenetics

7. AK is a 71-year-old female with lower-risk MDS being treated with watch and wait strategy. AK becomes fatigued and her hematologist orders blood work. Which of the following lab values is needed to proceed with ESA support?

A. Neutrophils <1,000 cells/mm^3 (1×10^9/L)

B. Platelets <50 cells/mm^3 (0.05×10^9/L)

C. EPO level <500 mU/mL (U/L)

D. Hemoglobin <8 g/dL (80 g/L; 4.97 mmol/L)

8. CH is a 57-year-old male with MDS, a hypocellular marrow, and refractory anemia of short duration. Which of the following bone marrow results should be present for the selection of immunosuppressive therapy to treat MDS?

A. TP53

B. Normal cytogenetics

C. Del(5q)

D. Trisomy 8 with HLADR15+

9. TK has lower-risk MDS and is being treated with ATG plus cyclosporine. On day 8, TK develops fever, rigors, and malaise. TK is started on antibiotics. Which of the following is the most appropriate additional recommendation to manage TK?

A. Prednisone

B. Filgrastim

C. Acetaminophen

D. Maintenance intravenous fluids

10. Both azacitidine and decitabine are FDA-approved therapies for MDS. Which of the following outcomes supports the use of azacitidine over decitabine despite the fact that no head-to-head clinical trials are available?

A. Overall response rate

B. Overall survival

C. Hazard rate

D. Complete response

11. Which of the following drug class are azacitidine and decitabine part of?

A. Immunomodulating agents

B. Erythropoietin stimulating agents

C. Anthracyclines

D. Hypomethylating agents

12. PB is a 76-year-old man being treated with azacitidine. His oncologist asks you whether or not a bone marrow biopsy should be scheduled when PB completes cycle 1. Which of the following is the best response to this inquiry?

A. A bone marrow biopsy should be scheduled after cycle 1.

B. A bone marrow biopsy is not necessary.

C. It takes 4 to 6 cycles to observe a response and a bone marrow biopsy should be scheduled after allowing time to respond.

D. A CBC with differential can be exclusively used to monitor PB's MDS.

13. Which of the following is the only potentially curative treatment modalities for MDS patients who are candidates for therapy?

A. Allogeneic hematopoietic stem cell transplantation

B. Chimeric antigen receptor T-cells

C. Donor lymphocyte infusion

D. Autologous hematopoietic stem cell transplantation

14. MG is a 74-year-old woman with high-risk MDS that is transfusion dependent. MG has a lifetime transfusion history of 25 PRBC transfusions. Her ferritin level is 3,000 ng/mL (μg/L; 6,740 pmol/L) and she presents with complaints of SOB. Which of the following is an appropriate supportive care consideration for MG?

A. Apheresis

B. Deferoxamine

C. Iron supplementation

D. Albuterol

15. Which of the following treatments is associated with MDS?

A. Doxorubicin

B. Cytarabine

C. Cetuximab

D. Vaccination

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** An 88-year-old man with a history of non-Hodgkin lymphoma treatment treated with chemotherapy plus radiation because of his age and lymphoma treatments, which likely included an alkylating agent (cyclophosphamide) + topoisomerase II inhibitor (doxorubicin) as part of standard-of-care chemotherapy and radiation.

2. **C.** Myelosuppression is the dose-limiting toxicity of azacytidine and decitabine.

3. **D.** MDS is a disease of older adults with a median age at diagnosis of 76 years and a slight male predominance. Thus, the most likely medication-related problem is polypharmacy as older adults tend to have more comorbid conditions.

4. **C.** Lenalidomide is an analog of thalidomide, which was removed from the market in the mid-twentieth century after reports of teratogenicity. It was later reintroduced for treatment of HIV-related leprosy and later MDS with the implementation of a REMS to prevent teratogenic effects.

5. **B.** Lenalidomide is renally excreted and requires dose adjustment for kidney dysfunction. Given that JV is experiencing acute kidney injury and it is not known if this condition will worsen, the best course of action would be to hold lenalidomide.

6. **A.** Lenalidomide studies have shown positive outcomes in MDS with del(5q) as a targeted therapy. See the "Immunomodulating Agents" section under the "Lower-Risk MDS Patients" section.

7. **C.** MDS patients with an erythropoietin level <500 mU/mL (U/L) had better outcomes with ESA support than those with higher levels in low-risk MDS without del(5q).

8. **D.** The National Institutes of Health has developed an algorithm to predict response to immunosuppressive therapy, and criteria include age younger than 60 years, hypocellular marrow, refractory anemia of short duration, **trisomy 8 as the sole cytogenetic abnormality, and HLA DR15 positive expression**. See the "Immunomodulating Agents" under the "Lower-Risk MDS Patients" section.

9. **A.** TK has nonspecific symptoms that could be related to infection and thus is on appropriate antibiotics. Given TK is already on antibiotics, and it is over 1 week status post treatment with ATG, TK could have symptoms of serum sickness and thus prednisone is appropriate.

10. **B.** Both azacitidine and decitabine have been demonstrated to provide benefits for the treatment of MDS. However, only azacitidine has been associated with improved overall

survival.

11. **D.** Azacitidine and decitabine are hypomethylating agents with effectiveness in the treatment of both low-risk MDS and certain forms of high-risk MDS.

12. **C.** Hypomethylating agents work by acting on epigenetic factors related to MDS. Given this mechanism of action, their effect on cell kill takes time and so it is most appropriate to assess response to hypomethylating agents after multiple cycles of treatment, typically 4 to 6, 28-day cycles.

13. **A.** Most treatments for MDS are palliative and the only curative treatment for MDS is allogeneic hematopoietic stem cell transplantation. However, not all MDS patients will be candidates for this treatment modality.

14. **B.** MG has symptoms that have been associated with iron overload, a lifetime transfusion history of 25 PRBC transfusions, and her ferritin level is elevated above 2,500 ng/mL (μg/L; 5620 pmol/L). She should be started on deferoxamine.

15. **A.** Doxorubicin is a topoisomerase II inhibitor and these agents have been associated with TR-MDS.

Chapter e161: Renal Cell Carcinoma

Erin B. Bailey; David D. Stenehjem

KEY CONCEPTS

KEY CONCEPTS

① Renal cell carcinoma (RCC) predominantly occurs later in life, with about 70% of all cases diagnosed between the ages of 55 and 84 years.

② Established risk factors for RCC include smoking, obesity, hypertension, and inherited susceptibility.

③ Inactivation of the von Hippel-Lindau tumor suppressor gene (*VHL*) is the hallmark of the most common type of RCC, the clear cell histologic subtype.

④ More than 50% of RCC cases are diagnosed by incidental findings on routine imaging for unrelated reasons.

⑤ The Memorial Sloan-Kettering Cancer Center (MSKCC) Prognostic Factors Model for Survival and International Metastatic Renal Cell Carcinoma Database Consortium (IMDC) Criteria classifies patients into favorable-, intermediate-, and poor-risk groups based on clinical factors, and can predict survival among both untreated patients and those treated with immunotherapy and/or targeted agents.

⑥ Surgical excision of the primary tumor, either by radical or partial nephrectomy, is the preferred treatment modality for patients with stage I-III RCC, but some patients with stage IV disease may also benefit from surgery.

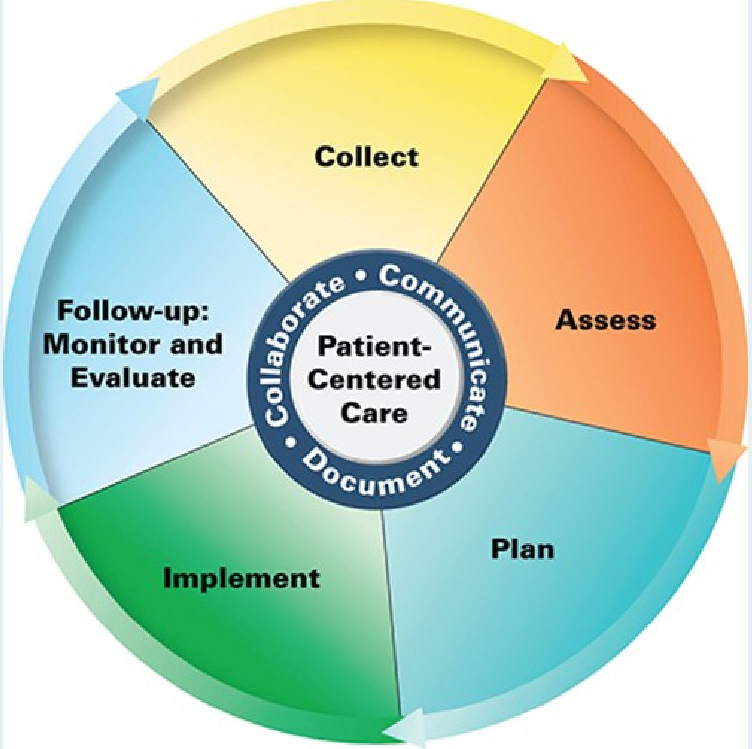
⑦ Immunotherapy (programmed cell death protein-1 [PD-1], PD-ligand 1 [PD-L1] and cytotoxic T lymphocyte-associated antigen-4 [CTLA-4] inhibitors) and targeted therapy (multikinase inhibitors, mammalian target of rapamycin [mTOR] inhibitors, and vascular endothelial growth factor [VEGF] inhibitors) are integral components of the management of advanced or metastatic RCC with unique mechanisms of action and adverse drug reaction profiles.

⑧ First-line treatment options for metastatic RCC (mRCC) are chosen based on patient-specific factors and include small molecule tyrosine kinase inhibitors (sunitinib, pazopanib, axitinib, cabozantinib), an mTOR inhibitor (temsirolimus), and immune checkpoint inhibitor combinations (ipilimumab plus nivolumab, nivolumab plus cabozantinib, pembrolizumab plus axitinib, and pembrolizumab plus lenvatinib).

⑨ In patients who progress after first-line treatment, multikinase inhibitors cabozantinib, axitinib, and lenvatinib (in combination with everolimus) or immunotherapy with nivolumab may be considered. Combination of nivolumab and ipilimumab and combination immunotherapy with a multikinase inhibitor (eg, pembrolizumab plus axitinib) are also options. A multikinase inhibitor, tivozanib, is an option for patients who have received two or more prior therapies.

PATIENT CARE PROCESS

Patient Care Process for Renal Cell Carcinoma



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (age, weight, height and past medical history)
- Laboratory assessment with a complete blood count (CBC), comprehensive metabolic panel, liver function tests (LFTs), and lactate dehydrogenase (LDH), and calculate the corrected calcium
- Social history (including tobacco and alcohol use) and family history (including cancer history)
- A comprehensive medication list that includes prescribed and over-the-counter medications, herbal remedies, dietary supplements, and vitamins
- Additional information pertinent to patient prognosis (see Table e161-3)

Assess

- Tumor staging based on TNM criteria and histology (see Tables e161-1 and e161-2) and performance status to evaluate the ability to undergo treatment
- Patient prognostic risk score by IMDC or MSKCC criteria (see Table e161-3)
- Potential moderate and serious drug-drug interactions (see Table e161-4)

Plan*

- Treatment selection, which includes dose, route, frequency, and duration
- Establish monitoring parameters, frequency of monitoring, and plan for follow-up in clinic
- Coordination of medication acquisition with insurance, specialty pharmacy, and in certain situations with the pharmaceutical industry (eg, free drug for indigent patients)

- Medication administration education and determine barriers to adherence for orally administered targeted therapies

Implement

- Patient education on all facets of the treatment plan, including management of adverse drug reactions. For immunotherapies, patient education will also include when to contact providers (instead of self-care) should adverse drug reactions arise.
- For orally administered targeted therapies, educate on administration, handling precautions, medication adherence, and also processes and procedures with specialty pharmacy.
- Schedule follow-up labs (eg, CBC, comprehensive metabolic panel, LFTs), and schedule appointment for adverse drug reaction and adherence assessment.

Follow-Up

- Follow-up frequency following pharmacotherapy initiation should be tailored to the medication-specific monitoring requirements and incidence and severity of treatment-related adverse drug reactions (see Table e161-5). Additional follow-up may be required for monitoring the effects of drug-drug interactions.
- Efficacy monitoring is based on serial imaging results. Frequency of imaging can range between 6 and 16 weeks, and may be dependent on patient-specific clinical factors, cancer-related symptoms, rate of cancer progression, and type of therapy received.

Monitor:

- Monthly physical exam to evaluate the recurrence of disease-related symptoms and treatment-related adverse drug reactions
- Monthly monitoring of medication adherence to regimens containing orally administered targeted therapies

Evaluate:

- Monthly evaluation of laboratory values to monitor disease response and/or treatment-related adverse drug reactions. Laboratory monitoring is medication specific and may be more frequent following treatment initiation or while managing laboratory-related adverse events.
- Evaluation of imaging studies (computed tomography [CT], positron emission tomography [PET], magnetic resonance imaging [MRI]) every 6 to 16 weeks to monitor disease response, stabilization, or progression. Treatment is continued with response or stable disease.

[*] *Collaborate with patients, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

- Develop a study table showing appropriate first-line treatment options for advanced and metastatic clear cell RCC in different patient groups. This summary table should include factors included in the MSKCC and IMDC Criteria prognostic scoring tools. The summary table should also include how these prognostic tools stratify patients into favorable/low-, intermediate- and poor-risk categories. This summary table should include both orally and intravenously administered pharmacotherapeutic options. The intent of this activity is to help students practice their skills in the Collect and Assess steps of the patient care process and apply them to patients with advanced and metastatic RCC.

INTRODUCTION

Renal cell carcinoma (RCC) represents about 2% to 4% of all adult malignancies and is the most common type of malignancy of the kidney and renal pelvis. Few treatment options existed, and those that were available had modest activity and were poorly tolerated by patients. However, treatment for the disease has been revolutionized by targeted agents and immunotherapies that were developed based on an increased understanding of RCC pathophysiology. Clear cell is the predominant histologic subtype of RCC (about 80% of all cases) and is characterized by the inactivation of the von Hippel-Lindau (*VHL)* tumor suppressor gene located on chromosome 3p25. *VHL* inactivation leads to increased production of growth factors, such as vascular endothelial growth factor (VEGF), transforming growth factor (TGF), platelet-derived growth factor (PDGF), and others responsible for angiogenesis and cell growth.[1] Several targeted drugs have been approved as first- or subsequent-line therapy for RCC in recent years.[2–11] Each drug is an example of targeted therapy against growth factors important in the pathophysiology of RCC, and has yielded much needed progress in a disease with few therapeutic options. Additionally, immune checkpoint inhibitors, such as avelumab, ipilimumab, nivolumab, and pembrolizumab, have emerged as treatment options, with novel mechanisms of action and adverse drug reaction profiles. Immune checkpoint inhibitors work by amplifying T-cell response against tumor-specific antigens. RCC serves as an example of the rational development of targeted agents based on knowledge of tumor biology and molecular signaling pathways for the treatment of other malignancies.

EPIDEMIOLOGY

In this chapter, the term “women” and “men” are used to reflect gender identified in previous research studies and other literature on kidney cancer and to recognize the biological sex of individuals at birth. In doing so, we recognize that not all patients with kidney cancer identify as females or males at the time of diagnosis and treatment of kidney cancer. About 79,000 new cases of kidney and renal pelvis cancer are diagnosed each year in the United States, with almost two-thirds of these cases occurring in men.[12] Nearly 14,000 people in the United States die of kidney cancer each year.[12] Kidney cancer is the sixth most common cancer in men, and the number of new cases diagnosed each year is similar to non-Hodgkin lymphoma and cancers of the head and neck. In women, kidney cancer is the eighth most common cancer, occurring at a rate similar to the rates for leukemias and pancreatic cancers.[12] The incidence of RCC has increased over the past three decades, although the rates of death have been falling an average of 1.4% between 2009 and 2018. The incidence of RCC has increased more rapidly in Black individuals than White individuals and more rapidly in women than men, although rates in women appear to have stabilized in recent years. In the United States, between 2013 and 2017, the age-adjusted incidence rate in Black men was 24.5, White men 23.0, Black women 12.2, and White women 11.4 per 100,000 person-years.[13] This increase may be related to improved imaging techniques and greater use of these imaging modalities, although the higher prevalence of some risk factors may also explain the increased incidence.

① Kidney cancer is most commonly diagnosed between the ages of 55 and 74 years, with a peak in the sixth and seventh decades of life.[13] Nearly 70% of all cases of kidney cancer are diagnosed in people between the ages of 55 and 84 years, with around 3% of all cases diagnosed in patients younger than 34 years. The median age at diagnosis is 64 years old.[13]

One of the primary factors influencing overall survival is the extent of disease spread. When the tumor is confined to the kidney at the time of diagnosis, surgical resection can result in a five-year overall survival of about 93%.[12] However, that figure falls to 71% when localized spread has occurred beyond the kidney.[12] Approximately 20% to 30% of patients with localized disease will relapse within three years following surgery, and about 30% of RCC patients will present initially with metastatic disease.[13] The five-year survival rate for patients diagnosed with metastatic disease is about 14%.[13] Median overall survival for RCC has improved over the past two decades, which could be attributed to improved screening and early detection of smaller tumors, the use of cytoreductive nephrectomy prior to the use of systemic therapy in advanced disease, or the availability of multiple new agents that target angiogenic, immunogenic, and oncogenic signaling pathways.

ETIOLOGY

The incidence rates of RCC vary more than 15-fold worldwide, with the highest incidence rates in the more developed regions of North America, Europe, and Australia and the lowest in Africa and Asia, which suggests that lifestyle and environment could be important factors underlying the development of RCC.[14] Established risk factors associated with RCC include smoking, obesity, hypertension, and inherited susceptibility.[14,15]

② Smoking remains the most consistently established risk factor and is responsible for 10% to 30% of RCC diagnoses.[14] Smoking is associated with a relative risk of 1.54 for men and 1.22 for women, with a strong dose-dependent relationship. Heavy smoking, defined as 21 or more cigarettes per day, increases the relative risk (2.03 and 1.58, respectively). Smoking cessation reduces the risk of RCC, with a 15% to 30% decrease in patients who have quit smoking for 10 to 15 years, and a 50% decrease for those who have quit for 30 years or more.[16]

Obesity is also an established risk factor in RCC, based on multiple prospective cohort studies. A large cohort study that included over nine million participants and 15,000 cases of kidney cancer found an increased relative risk of 1.77 in participants who were obese (BMI greater than 30 kg/m^2), and an increased relative risk of 1.28 in those who were overweight (BMI 25-29.99 kg/m^2). The risk of kidney cancer increases linearly with increasing BMI, with a 4% increased risk for every 1 kg/m^2 increase in BMI.[17] About 30% to 40% of RCC cases may be attributed to obesity, which suggests that increasing rates of obesity in the United States may be partially responsible for the increased incidence of RCC observed over the past three decades.[18] Numerous mechanisms that could explain the link between obesity and RCC development have been proposed, but none have yet been definitively validated. One plausible hypothesis has linked obesity to increased lipid peroxidation, which can result in carcinogenesis of the proximal renal tubules. Byproducts of the lipid peroxidation pathway can result in deoxyribonucleic acid (DNA) adducts in the kidney, which lead to oncogene and tumor suppressor gene mutations, and eventually to malignancy.[19] In addition, adipose tissue impacts the metabolism and endocrine environment in the body. Increased adipose tissue can lead to chronic states of inflammation, increased insulin and insulin-growth factor 1, and increased estrogen and decreased adiponectin, all of which are associated with tumorigenesis.[20] Finally, the kidneys of obese men and women are more susceptible to carcinogenesis because of higher glomerular filtration rates, increased renal perfusion, and atrophic scarring of the kidneys.[18]

The risk of RCC development is associated with increased duration and severity of elevated blood pressure. Patients with diastolic blood pressure greater than 90 mm Hg had a 56% increased risk for development of RCC as compared to those with diastolic blood pressure less than 90 mm Hg. A systolic blood pressure greater than 160 mm Hg was associated with a 54% increased risk of RCC development compared with systolic blood pressure less than 120 mm Hg.[21] The exact pathophysiologic mechanism underlying the causal relationship between hypertension and RCC has yet to be conclusively identified and validated, but it is believed to be related to hypertension-induced renal injury and lipid peroxidation.[17] The use of antihypertensive medications do not appear to be associated with RCC development.

A well-defined link between RCC development and an inherited susceptibility has also been described. Although most RCC cases are not associated with hereditary factors and are considered “sporadic,” 2% to 3% of RCC cases are secondary to inherited syndromes.[22] Hereditary RCC is most commonly the result of an autosomal dominant transmission of a pathogenic mutation from a carrier to the offspring. Initially, one carrier parent has one healthy chromosome without the pathogenic mutation and one chromosome with the mutation. When the carrier has offspring with a healthy individual with two unaffected chromosomes, the offspring will have a 50% chance of also being a carrier. These carriers with one unaffected chromosome and one chromosome with a pathogenic mutation are at a significantly higher risk of developing RCC after being exposed to additional somatic mutations. The most common examples of hereditary RCC include VHL syndrome and Birt–Hogg–Dubé syndrome.[22]

SUBTYPES AND PATHOPHYSIOLOGY

RCC arises from the epithelium lining the renal tubules, and at least 85% of all malignancies arising in the kidney and renal pelvis can be classified as RCC.[23] The renal pelvis is less commonly affected, and only about 12% of the diagnosed kidney cancer cases each year are confirmed cancers of the renal pelvis. Other rare malignancies, affecting other parts of the kidney (eg, medullary and collecting duct carcinomas), make up the remaining 3%. The subtypes of RCC include clear cell, papillary (also known as chromophilic), chromophobe, and oncocye. Each subtype has a unique genetic pathophysiology that results in a different clinical course and response to therapy.[23]

Clear Cell Subtype: The Role of the VHL Gene

The most common histological subtype of RCC is clear cell RCC (about 80% of all RCC cases).[23,24] Clear cell RCC typically affects the proximal tubule of the kidney and is more likely to metastasize than other subtypes. An association between tumors with clear cell histology and losses in the short arm of chromosome 3 eventually led to the discovery of the gene responsible for this histologic subtype. Subsequently, *VHL* was mapped to 3p24-25.[25,26] Inactivation of the *VHL* tumor suppressor gene is now recognized as the hallmark of clear cell RCC. The Knudson and Strong two-hit model explains that the sequential inactivation of both copies of *VHL* can lead to the development of clear cell RCC.[27] In patients with sporadic disease, the two copies of *VHL* present in a healthy kidney can be inactivated via loss of chromosome 3p, epigenetic gene silencing (eg, hypermethylation of the *VHL* promoter), and genetic mutations (eg, missense mutations, nonsense mutations, or premature gene truncations). Additional mutations can result in a single, unilateral tumor. In patients with hereditary disease, one copy of *VHL* has already suffered a loss of function due to inherited germline mutations.

Thus, fewer sporadic events are then required for the inactivation of the remaining *VHL* copy. This at least partially explains why patients with hereditary disease are more likely to present with multicentric, bilateral tumors.[22,23]

3 *VHL* codes for the VHL protein (pVHL), which is expressed ubiquitously throughout the body, and is part of the complex that selects substances for ubiquitination and subsequent proteasomal degradation.[28] Because of this role, pVHL regulates cellular response to oxygen. Under normoxic conditions, hypoxia-inducible factor (HIF)-1α and HIF-2α are marked for ubiquination. Hydroxylated HIF-1α and HIF-2α bind to pVHL and are then degraded by the proteasome (see Fig. e161-1). However, when the cellular environment is hypoxic, HIF-1α and HIF-2α are not hydroxylated and do not bind to pVHL. The unbound HIF-1α and HIF-2α can then initiate transcription of hypoxia-inducible genes in the cell nucleus, which enables the cell to adapt and survive a hypoxic insult (see Fig. e161-2).[23,28] In the case of clear cell RCC, when *VHL* is mutated or silenced, pVHL is unable to bind and target HIF-1α and HIF-2α for degradation, regardless of the oxygen present in the environment. As a result, HIF-1α and HIF-2α levels increase, and they are then able to initiate transcription of pro-angiogenic and pro-mitogenic genes, including *VEGF*, *PDGF*, *TGF*, as well as genes that encode glucose transporters, and erythropoietin (see Fig. e161-3).[23,28] Eight of the ten targeted agents approved by the US Food and Drug Administration (FDA) for the treatment of RCC target these genes, and are discussed later in the chapter.

FIGURE e161-1

The role of pVHL and HIF: normal oxygen, normal *VHL*. In a normal oxygen environment, HIF is hydroxylated (OH). This enables binding of the VHL protein and subsequent attachment of a polyubiquitin chain, which is a process called ubiquitination (Ub). This allows the ubiquitin-tagged HIF to be recognized for destruction by the proteasome. The proteasome acts as a garbage disposal for compounds labeled by the ubiquitination process. An illustration shows that HIF and VHL, each bonded to OH, is attached to ubiquitin ligase, in which the HIF is bonded to a chain of four Ub. This leads to the HIF, consisting of two OH and a chain of four Ub, attaching itself to proteasome.

FIGURE e161-2

The role of *VHL* and HIF-1α and HIF-2α: low oxygen, normal *VHL*. In a low oxygen environment, the cell wants to increase production of substances to promote a switch to anaerobic metabolism, including enzymes involved in glycolysis and glycerol metabolism. In the situation depicted in this figure, HIF-1α is not hydroxylated and cannot bind to VHL. HIF-1α is then able to translocate into the nucleus of the cell. In the nucleus, HIF-1α combines with the HIF-β subunit and the p300 transcriptional cofactor on the hypoxia response element (HRE) that promotes the transcription of HIF-1α target genes. More than 100 genes can be activated by this complex, and include *VEGF*, *PDGF*, transforming growth factor (*TGF*), erythropoietin (*EPO*), and glucose transporter 1 (*GLUT1*). An illustration shows that when VHL inhibits HIF-1 alpha, it enters the cell nucleus, and attaches itself to HIF-beta, p300, and HRE. These undergo transcription, resulting in the release of HIF target genes, such as VEGF, PDGF, TGF, EPO, and GLUT1.

FIGURE e161-3

The role of *VHL* and HIF-1α: normal oxygen, mutated *VHL*. When the *VHL* gene is mutated, it encodes a protein that is not able to bind to the hydroxylated HIF-1α, regardless of the presence of oxygen in the environment. Because HIF-1α is not bound to VHL, it is not destroyed by the proteasome, and therefore is free to translocate into the nucleus, combine with the HIF-β subunit and the p300 transcriptional cofactor on the HRE, and initiate gene transcription. Because a hypoxic situation is not present, transcription of genes involved in angiogenesis, cellular survival, and glucose metabolism can result in an oncogenic process. (*ADRP*, adipose differentiation-related protein [responsible for neutral lipid accumulation in the cell cytoplasm, resulting in the clear cell appearance]; *EPO*, erythropoietin; TGF, transforming growth factor). An illustration shows that when VHL activates HIF-1 alpha, attached with two OH groups, it enters the cell nucleus, and attaches itself to HIF-beta, p300, and HRE. These undergo transcription, resulting in the release of HIF target genes, such as VEGF, PDGF, TGF, EPO, and ADRP.

In addition to pVHL, other growth factors and cell adhesion pathways control HIF-1α and HIF-2α activity.[28] TGF is a ligand for the epidermal growth factor receptor and, upon binding, activates the phosphatidylinositol 3-kinase (PI3K)/protein kinase B (AKT)/mammalian target of rapamycin (mTOR) pathway, in addition to other protein kinase pathways. Activation of the mTOR pathway increases the production of HIF-1α *and* HIF-2α, which can drive the oncogenic processes described earlier.[28,29] The mTOR pathway is another target for RCC treatments, which are discussed later in the chapter.

Papillary Subtypes

Papillary subtypes account for 5% to 10% of RCC cases and occur in the renal proximal tubules. They are most commonly diagnosed when the disease is localized, and thus have a more favorable prognosis than the clear cell subtype. Unlike mutations in a single tumor suppressor gene that predominantly drive the development of clear cell RCC (eg, *VHL*), papillary RCC has been associated with multiple genetic abnormalities. These tumors are further subclassified into types 1 and 2. Papillary type 1 patients are more likely to have multiple, lower grade, bilateral tumors, and have a better prognosis. In contrast, patients with papillary type 2 are more likely to present with singular, higher grade, unilateral tumors, and have a poorer prognosis.[23]

More than 80% of hereditary papillary type 1 RCC cases are associated with germline activating mutations in the mesenchymal–epithelial transition (*MET*) oncogene, located at chromosome 7q31-34.[30] These mutations are responsible for about 13% of sporadic type 1 disease, but chromosome 7 duplications are in 75% of these cases, further supporting the oncogenic role of *MET*.[28] *MET* encodes the c-MET receptor, and activation of the c-MET receptor results in increased cell proliferation and motility, and decreased cellular apoptosis.[29] Stabilization of HIF-1α and HIF-2α can also play a role in the oncogenic potential of the c-MET receptor.[31]

The papillary type 2 subtype occurs in patients with hereditary leiomyomatosis, which initially presents as multiple skin and uterine leiomyomas when patients are in their 20s and 30s, and eventually results in the formation of RCC. The gene associated with papillary type 2 RCC is the fumarase hydratase (*FH*) gene, located at chromosome 1q42.3-45. *FH* is a tumor suppressor gene that encodes the FH enzyme, which is responsible for catalyzing the conversion of fumarate to malate in the Krebs cycle. *FH* is predominantly inactivated by loss-of-function mutations, which ultimately results in HIF-1α and HIF-2α stabilization and subsequent RCC tumorigenesis.[32]

Chromophore and Oncocytoma Subtypes

The chromophore and oncocytoma subtypes combined are responsible for 5% to 10% of all RCC cases and occur in the intercalated cells of the collecting system of the kidney. Both are associated with a wide variety of chromosomal deletions and translocations. Oncocytomas are relatively benign and rarely metastasize.[23] Hereditary forms of chromophore and oncocytoma RCC are associated with the Birt–Hogg–Dube syndrome, which is characterized by hair follicle fibrofolliculomas of the face and neck and lung cysts in 15% to 30% of affected individuals. The *FLCN,* or folliculin, tumor suppressor gene is located on the short arm of chromosome 17 and is responsible for encoding the protein folliculin.[19]

Sarcomatoid Dedifferentiation

Sarcomatoid RCC is not classified as a unique tumor subtype; however, it refers to a form of tumor dedifferentiation consisting of spindle shaped cells, high cellularity and cellular atypia, and sarcoma cell features/architecture.[33] Therefore, sarcomatoid features can occur across all histological subtypes and occurs in 5% to 15% of all patients with RCC. Patients with sarcomatoid RCC are more likely to present with advanced stage disease and historically have rapid tumor growth and reduced prognosis with low response rates to targeted therapies (VEGF receptor [VEGFR]-tyrosine kinase inhibitors [TKIs] and mTOR inhibitors).[33] However, immunotherapy is changing this paradigm with increased response rates observed over VEGFR-TKIs.[34]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Renal Cell Carcinoma

Symptoms

- Flank pain
- Fatigue
- Absence of symptoms is often seen with early disease

Symptoms of Disease Progression/Metastatic Disease

- Bone pain
- Pulmonary symptoms, including shortness of breath and cough
- Types of symptoms differ depending on location of disease spread

Signs

- Weight loss
- Anemia
- Hypertension
- Fever
- Lower extremity edema
- Hematuria
- Palpable abdominal mass

Sign of Advanced Disease

- Adenopathy

Diagnostic Tests

- CBC with differential
- Serum calcium
- Serum creatinine (SCr)
- LFTs
- Alkaline phosphatase
- LDH
- Urinalysis
- Chest x-ray
- Contrast and noncontrast CT or MRI of the abdomen pelvis
- Bone scan, brain MRI, chest CT in select cases
- Core needle biopsy in select cases

DIAGNOSIS

④ Imaging modalities, such as CT, PET, and MRI scans, are widely used in the medical workup of numerous conditions. As a result, at least 50% of new RCC diagnoses are incidental findings when patients undergo radiographic imaging for reasons unrelated to RCC. This is a sharp increase from 1970, when only 10% of new diagnoses were incidental.[35] Few patients present with the “classic triad” of hematuria, flank pain, and a palpable abdominal mass. Incidental diagnoses, or diagnoses made in the absence of the “classic triad” signs and symptoms that were historically associated with RCC, are usually smaller in size, lower stage, and more localized than those seen in patients who present with these signs and symptoms. In addition to the “classic triad,” patients commonly present with nonspecific signs and symptoms, including fatigue, weight loss, anemia, hypertension, fever, and lower extremity edema.[35] Distant metastases predominantly occur in the lung, bone, liver, adrenal gland, and brain. Adenopathy and pulmonary symptoms are indicators of metastatic spread to the mediastinum or lung parenchyma. Elevated alkaline phosphatase or bone pain may indicate bone metastases, while neurological symptoms (eg, nausea, headaches, vision changes) may indicate brain metastases.[15]

As previously discussed, RCC development can be either sporadic or hereditary. Several differences exist between the two etiologies in terms of development patterns. Sporadic RCC most often presents as a single tumor affecting one kidney in a patient who is at least 60 years of age. These lesions may or may not be cystic in histology, and a family history is usually not reported. In contrast, those with a hereditary etiology more commonly present with numerous cystic tumors that affect both kidneys. These patients are more likely to be younger than 50 years, and they may present with other primary malignancies or have a strong family history of RCC.[35]

Laboratory evaluation should include a CBC with differential, serum calcium, SCr, LFTs, alkaline phosphatase, LDH, and urinalysis. Imaging studies are also performed to further characterize the renal tumor, assess the involvement of the inferior vena cava, and determine the patient’s disease stage. Additional imaging studies, such as a bone scan or brain MRI, may be pursued depending on symptoms at presentation. Core needle biopsy is used only in rare selected cases of small lesions to guide surveillance, cryosurgery, and radiofrequency ablation strategies.[15]

STAGING AND PROGNOSIS

Factors associated with poor prognosis include positive margins after surgery, evidence of metastatic spread, presence of sarcomatoid architecture, tumor subtype, tumor grade, and tumor stage, with the latter being the most powerful prognostic indicator.[36] The eighth edition of the American Joint Committee on Cancer (AJCC) staging classification considers tumor size, number of lymph nodes involved (TNM), and the presence or absence of distant metastases.[37] Subdivisions in the tumor classification further describe the structures of the kidney that have been invaded by the tumor, including the adrenal gland, Gerota's fascia (the layer of connective tissue surrounding the kidneys), and perinephric fat that lies between the fascia and renal capsule.[37] Table e161-1 summarizes the AJCC TNM staging definitions and Table e161-2 shows the TNM stage and corresponding five-year overall survival rates.

TABLE e161-1

AJCC Staging and End Results Reporting TNM Staging Definitions

Primary Tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor ≤ 7 cm in greatest dimension, limited to the kidney
T1a	Tumor ≤ 4 cm in greatest dimension, limited to the kidney
T1b	Tumor > 4 cm but ≤ 7 cm in greatest dimension, limited to the kidney
T2	Tumor > 7 cm in greatest dimension, limited to the kidney
T2a	Tumor > 7 cm but ≤ 10 cm in greatest dimension, limited to the kidney
T2b	Tumor > 10 cm in greatest dimension, limited to the kidney
T3	Tumor extends into major veins or perinephric tissues, but not into the ipsilateral adrenal gland and not beyond Gerota's fascia
T3a	Tumor grossly extends into the renal vein or its segmental (muscle containing) branches, or tumor invades perirenal and/or renal sinus fat but not beyond Gerota's fascia
T3b	Tumor extends into the vena cava below the diaphragm
T3c	Tumor extends into vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumor invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland)
Regional Lymph Nodes (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node(s)
Distant Metastasis (M)	
M0	No distant metastasis
M1	Presence of distant metastasis

TABLE e161-2

AJCC Staging and Five-Year Overall Survival Results by Location[38]

Stage	T	N	M	Five-Year Overall Survival (%)
I	T1	N0	M0	Local: 92.6
II	T2	N0	M0	
III	T1	N1	M0	Regional: 70.4
	T2	N1	M0	
	T3	Nx	M0	
	T3	N0	M0	
	T3	N1	M0	
IV	T4	Any N	M0	Distant: 13.0
	Any T	Any N	M1	

M, metastasis; N, node; T, tumor.

Data from Howlader N, Noone AM, Krapcho M, et al. eds. SEER Cancer Statistics Review, 1975-2017, National Cancer Institute. Bethesda, MD. Available at: https://seer.cancer.gov/csr/1975_2017/, based on November 2019 SEER data submission, posted to the SEER web site, April 2020.

⑤ In patients with metastatic RCC (mRCC), the MSKCC Prognostic Factors Model for Survival was developed from a retrospective analysis of 670 patients with advanced RCC from 24 different trials at MSKCC between 1975 and 1996. The model identified five factors associated with poor prognosis: Karnofsky performance status, LDH, hemoglobin, corrected serum calcium, and nephrectomy status (later interchanged with duration of time from diagnosis to initial treatment). Patients with none of the poor prognostic risk factors are considered low-risk, patients with one or two factors are considered intermediate-risk, and three or more factors are poor-risk (see Table e161-3). In this analysis, 25% of patients were classified as low-risk (median overall survival of 20 months), 53% were intermediate-risk (median overall survival of 10 months), and 22% were poor-risk (median overall survival of 4 months). Three-year overall survival for the low-, intermediate-, and poor-risk groups was 31%, 7%, and 0%, respectively.[39] This model has been validated externally.[40] In an updated analysis, the IMDC prognostic model evaluated patients with mRCC treated with VEGF pathway-targeting agents. The IMDC prognostic model confirmed the importance of hemoglobin, corrected serum calcium, Karnofsky performance status, and time from diagnosis to treatment as prognostic factors for overall survival. Elevated neutrophil and platelet counts were also independent survival prognostic factors. Of the 586 evaluable patients treated with targeted agents (sunitinib, sorafenib, or bevacizumab), 23% were favorable-risk (overall survival that was not reached after a median follow-up of 24.5 months), 51% were intermediate-risk (median overall survival of 27 months), and 26% were poor-risk (median overall survival of 8.8 months). Corresponding two-year overall survival rates for the favorable-, intermediate-, and poor-risk groups were 75%, 53%, and 7%, respectively.[41] The IMDC model has subsequently been externally validated.[42]

TABLE e161-3

Prognostic Risk Scoring Tools

MSKCC Poor Prognostic Tool	
• KPS <80% • Low serum hemoglobin (<13 g/dL [130 g/L; 8.07 mmol/L] for men and <11.5 g/dL [115 g/L; 7.14 mmol/L] for women) • Elevated corrected calcium (>10 mg/dL [2.50 mmol/L]) • Elevated serum LDH (≥300 U/L [5.00 µkat/L] or 1.5 × ULN) • Absence of prior nephrectomy (a function of duration of time between diagnosis and start of therapy, with <1 year delay being considered a poor prognostic factor)	Low-Risk: 0 prognostic factors Intermediate-Risk: 1-2 prognostic factors Poor-Risk: 3 or more prognostic factors
IMDC Criteria	
• <1 year from the time of diagnosis to systemic therapy • KPS <80% • Hemoglobin < LLN • Calcium > ULN • Absolute neutrophil count > ULN • Platelet count > ULN	Favorable-Risk: 0 prognostic factors Intermediate-Risk: 1-2 prognostic factors Poor-Risk: 3 or more prognostic factors
KPS, Karnofsky performance status; LLN, lower limit of normal; ULN, upper limit of normal	

The MSKCC and IMDC criteria are used in practice to personalize therapy for patients and have been incorporated into the National Comprehensive Cancer Network (NCCN) guidelines. For example, axitinib plus pembrolizumab, cabozantinib plus nivolumab, ipilimumab plus nivolumab, lenvatinib plus pembrolizumab, and cabozantinib alone are first-line treatment options recommended for patients with intermediate or poor-risk disease (ie, based on prognostic risk scoring tools).[15] Further, the criteria are used to determine eligibility or stratification for clinical trials.

TREATMENT

Surgical excision of the renal tumor remains the primary method of local disease control, and is performed in patients with stage I, II, or III disease.[15] In patients with advanced or metastatic disease, first-line treatment options for patients with favorable prognostic risk include combination TKIs plus immune checkpoint inhibitors, combination immune checkpoint inhibitors, and single-agent TKIs (Fig. e161-4). First-line treatment options for patients with intermediate- or poor-risk disease include combination TKIs plus immune checkpoint inhibitors, combination immune checkpoint inhibitors, single-agent TKIs, and an mTOR inhibitor (temsirolimus, poor-risk only). Subsequent-line treatment options include combination TKI + mTOR inhibitor, single-agent TKIs, combination TKIs + immune checkpoint inhibitors, combination immune checkpoint inhibitors, single-agent mTOR inhibitors, or VEGFA inhibitor. In select patients with normal organ function and excellent performance status, high-dose interleukin-2 may be considered in the first or subsequent-line settings.

Desired Outcomes

The goal of therapy for RCC depends on the stage of disease at diagnosis and other patient-specific factors, which include age, performance status, and comorbidities. In patients with localized disease confined to the kidney (stages I, II, and III), the initial treatment recommendation is surgical removal with curative intent. In patients with initially localized disease who undergo nephrectomy, 20% to 30% will relapse, with most relapses occurring in the first two years after surgery. When patients have metastatic disease, the goal of therapy is to control disease burden and prolong survival while maximizing quality of life. Even among patients with mRCC, survival outcomes depend on patient-specific prognostic factors and treatment selected based on prognostic risk.[41] The selection of each line of therapy, and even considering agents with differing mechanisms of action within the same line of therapy, should be weighed against the risks and benefits for each individual patient.

Optimizing quality of life is always a treatment goal for all treatment modalities. Symptoms differ based on disease stage, sites of distant disease, and treatment. Patients with bone involvement may experience pain in the areas of metastatic disease that can be addressed with the use of bone modifying agents (eg, bisphosphonates or denosumab), palliative radiation therapy, and optimized daily pain medication regimens. Adherence to orally administered targeted therapies should be emphasized, both in terms of taking the medication regularly as prescribed, but also following administration directions (eg, taking the targeted therapy with or without food, and avoiding interacting medications). Adverse drug reactions should also be aggressively addressed to optimize the benefits of therapy. Hypertension, skin-related effects, and diarrhea are common adverse drug reactions of the TKIs that target the three VEGFRs, while hypercholesterolemia and hyperglycemia are common adverse drug reactions associated with mTOR inhibitors. Adverse drug reactions can be prevented or mitigated with close monitoring and/or appropriate therapeutic interventions to improve tolerability, improve medication adherence, and optimize patient quality of life. The subjective nature of many of these adverse drug reactions and disease-related toxicities can make consistent assessment challenging, but clinical trials incorporating quality-of-life outcomes, based on validated patient-reported assessments, will improve both survival and quality of life for RCC patients.

Surgery

⑥ Surgery represents a viable treatment modality for many RCC patients regardless of stage. Surgical options include total excision of the entire kidney (radical nephrectomy) and nephron-sparing surgery. The type of surgery performed depends on numerous patient-specific factors, which include the size and location of the renal tumor, whether multiple tumors are present, and whether the patient has unilateral versus bilateral kidney tumors. Radical nephrectomy involves excision of the entire kidney, Gerota's fascia, and ipsilateral adrenal gland after ligation of the renal vein and artery. Radical nephrectomy is preferred for patients with large, central tumors (greater than 7 cm).[43] Regardless of the functional capacity of the remaining kidney, radical nephrectomy has been associated with a higher risk for patients developing chronic kidney disease, which explains why nephron-sparing techniques have become increasingly preferred in patients with T1 disease.[44]

The most common nephron-sparing procedure is partial nephrectomy, which, in appropriately selected patients, have equivalent outcomes as those seen in patients who received a radical nephrectomy.[45] Partial nephrectomy candidates are those with smaller lesions (usually less than 4 cm) that are located in the cortical region of the kidney. Patients with bilateral tumors and those with already compromised renal function are also candidates for partial nephrectomy. Nephron-sparing surgery can also be used to describe probe-based thermal ablation procedures such as radiofrequency ablation and cryoablation. These less invasive techniques appear to have similar rates of distant recurrence to partial nephrectomy, but numerous reports suggest higher rates of local recurrences.[46] Because radiofrequency ablation and cryoablation can result in localized fibrotic reactions, surgical salvage after relapse can be compromised, and these procedures are typically reserved for patients who are not surgical candidates but still desire aggressive localized therapy. In addition to surgical excision of the tumor, some surgeons recommend extended lymphadenectomy. The procedure is controversial when lymph node involvement is not apparent, but advocates of the procedure suggest that it can be prognostic because the discovery of positive nodal involvement on lymphadenectomy can predict the presence of distant metastatic disease (even after lymph nodes have been removed).[15,16] Nearly one-third of patients relapse after surgery, but clinical trials of adjuvant treatment with radiation, immunotherapy, and numerous targeted agents failed to improve relapse-free survival in patients who initially present with localized disease (stages I-III). As a result, most patients are managed with active surveillance after local treatment, with imaging of the chest and abdomen every 4 to 6 months after surgery and then as clinically indicated. This paradigm may be changing based on the results of the S-TRAC trial, which evaluated the use of adjuvant sunitinib in patients at high risk for disease recurrence after radical nephrectomy (stages III-IV). Patients who received sunitinib had a longer median disease-free survival as compared to those who received placebo (6.8 vs 5.6 year), but also experienced increased treatment-related adverse drug reactions and lower health-related quality of life scores. Overall survival data for the trial has not yet been reported, and the optimal patient population in which to give adjuvant sunitinib, especially considering the increased risk for treatment-related adverse drug reactions, remains controversial.[15,47]

Surgery is still used for patients with metastatic disease (stage IV) and may consist of surgical resection of the renal tumor, metastectomy (surgical removal of metastatic sites), or both. Ideal candidates are those who have minimal regional lymphadenopathy, and a solitary site of metastatic disease. Metastatic sites amenable to resection include the lung, bone, brain, and soft tissue.[15,48] Clinical trials in patients with mRCC who received interferon alpha had an overall survival benefit when patients were randomized to receive a cytoreductive nephrectomy followed by interferon alpha versus systemic treatment alone. Patients with mRCC involving only the lung, with favorable prognostic features, and with a performance status of 0 or 1 appear to benefit the most from nephrectomy followed by interferon alpha.[49] The exact mechanism for the apparent improvement in overall survival is unknown, but it has been hypothesized that nephrectomy may reduce total tumor burden, increase the time for the tumor to develop, and/or eliminate the primary source of immunosuppressive cytokines and tumor-producing growth factors. However, as response rates to systemic treatments improve, the role of surgery in mRCC is being challenged. In the CARMENA trial, intermediate- and poor-risk patients with mRCC who were treated with cytoreductive nephrectomy followed by sunitinib had noninferior overall survival rates, as compared to those treated with sunitinib alone, which contradicts the overall survival benefit seen with surgery in patients treated with interferon alpha.[50] These conflicting results suggest a patient-specific approach that balances prognostic factors, disease burden, choice of systemic treatment, and patient preferences when recommending cytoreductive nephrectomy in mRCC. Regardless of systemic treatment for mRCC, palliative nephrectomy may be an option for patients with symptoms (eg, hematuria) related to their primary tumor when removal can provide symptom relief.

Chemotherapy

Traditional cytotoxic therapy has minimal activity in the treatment of RCC. Numerous agents have been investigated, the most active being gemcitabine, vinblastine, and 5-fluorouracil. However, response rates of more than 4% to 6% were rarely observed with single agents.[23] Intrinsic resistance to chemotherapy may be partially explained by increased expression of the multidrug resistance gene 1 (*MDR1*), which encodes the P-glycoprotein (Pgp) transmembrane pump involved in drug efflux. Variable *MDR1* expression levels are observed among many normal human tissues and different tumor types, but normal kidney tissue and various RCC subtypes both express high *MDR1* levels.[51] RCC tumors with high levels of Pgp protein expression are resistant to several traditional cytotoxic chemotherapeutics. Overexpression of other drug transporter proteins, including other multidrug resistance-associated proteins, may also play a role in primary drug resistance and also in the development of secondary drug resistance. Alterations in glutathione metabolism and proteins involved with regulation of apoptosis are also possible reasons underlying resistance to traditional cytotoxic chemotherapy.[52]

Immunotherapy

⑦ Patients with RCC occasionally experience spontaneous regression of their disease, which has led researchers to hypothesize that RCC evokes a host immune response, which provides rationale for studying immunotherapy in RCC.[53] Interferon alpha and high-dose interleukin-2 were the standard of care for patients with mRCC prior to the targeted therapy era. Low response rates, few durable responses, and high rates of severe adverse drug reactions have limited their clinical utility over the past decade. Immune checkpoint inhibitors, including the programmed cell death protein-1 (PD-1) inhibitors such as avelumab, nivolumab, and pembrolizumab, and cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) inhibitors such as ipilimumab, have improved responses as compared to these earlier efforts to harness the immune system, and are now utilized in the frontline setting for mRCC and in combination with TKIs.

Interleukin-2 is a glycoprotein primarily produced by helper T lymphocytes that stimulate the growth of cytotoxic T lymphocytes. It has been associated with response rates of approximately 20%.[54] Although the complete response rate is ≤ 10%, complete and durable responses can be achieved.[54] The FDA-approved dose of interleukin-2 is 600,000 international units/kg IV over 15 minutes given every 8 hours for a maximum of 14 doses. After this initial treatment, the dose schedule is repeated nine days later for an additional 14 doses as tolerated. Because of significant interleukin-2–related adverse drug reactions, treatment delays and discontinuations are common. The most common reported adverse drug reactions include hypotension, diarrhea, chills, vomiting, dyspnea, and peripheral edema in addition to increases in bilirubin, SCr and electrolyte abnormalities.[55] Many of these effects are related to capillary leak syndrome. Inpatient administration, intensive monitoring and supportive care are required, and many institutions administer interleukin-2 in an intensive care setting. Many patients are not candidates for interleukin-2 therapy because of their age (older than 60 years), comorbidities, compromised organ function, and poor performance status. According to the NCCN guidelines, high-dose interleukin-2 is useful in certain circumstances in the first-line and second-line treatment setting for mRCC. In both scenarios, high-dose interleukin-2 should be reserved for patients with excellent performance status and no evidence of organ dysfunction.[15]

PD-1 is a receptor expressed on activated T-cells, while its ligand, PD-L1, is expressed on immune and tumor cells. When PD-L1 binds to PD-1, the activity of T-cells is downregulated. By blocking this interaction, either at the level of PD-L1 or the PD-1 receptor, these inhibitors allow T-cells to remain activated. Because this interaction occurs in the lymph nodes and at the tumor after antigen presentation, serious adverse drug reactions (eg, autoimmune adverse drug reactions that can occur throughout the body) are limited and more manageable.[56]

CTLA-4 receptor expression is upregulated when a cytotoxic T-cell is activated by an antigen-presenting cell. Repressive CTLA-4 receptors compete with co-stimulatory receptors (such as cluster of differentiation 28, or CD28) on the T-cell surface to bind co-stimulatory proteins (such as B7) expressed on the antigen-presenting cell. Binding of CTLA-4 to co-stimulatory receptors leads to repression, rather than activation of T-cells. Ipilimumab binds to CTLA-4, thus preventing down-regulation of T-cells at the step of antigen presentation. Because CTLA-4 inhibitors act on T-cells during activation, the frequency and severity of autoimmune adverse drug reactions from these agents are higher than with the PD-1 inhibitors.[56]

Ipilimumab (CTLA-4 inhibitor), in combination with nivolumab (PD-1 inhibitor), is a frontline treatment option for mRCC.[57] Ipilimumab 1 mg/kg plus nivolumab 3 mg/kg intravenously every 3 weeks for four cycles, followed by maintenance with nivolumab monotherapy at a dose of 3 mg/kg intravenously every 2 weeks until disease progression or intolerable adverse drug reaction is the FDA approved dosing regimen. The objective response rate is 42%, with 9% of patients achieving a complete response. In patients with intermediate- or poor-risk disease based on IDMC scores, the 18-month overall survival rate is 75%. Rates of discontinuation due to treatment-related adverse drug reactions are high (22%), which can influence patient selection for this regimen.[57] Additionally patients with intermediate- or poor-risk disease based on IDMC have improved efficacy outcomes compared to those with favorable risk disease. The FDA approved the combination of ipilimumab and nivolumab for frontline treatment of mRCC in April 2018. Current NCCN guidelines list ipilimumab plus nivolumab as a preferred first-line regimen in patients with intermediate- and poor-risk disease (see Fig. e161-4).[15]

Nivolumab is the only PD-1 inhibitor approved by the FDA as monotherapy for the treatment of mRCC. The median overall survival in mRCC patients treated with nivolumab who had previously received one or two prior antiangiogenic therapies is 25 months. The objective response rate with nivolumab in this setting is 25%. Grade 3 or 4 adverse drug reactions occur in 19% of patients treated with nivolumab. The most common nivolumab treatment-related adverse drug reactions of any grade are fatigue, nausea, pruritus, diarrhea, decreased appetite and rash.[58] Single-agent nivolumab is recommended by NCCN as a second-line treatment option for clear cell, and a first-line option for patients with mRCC non-clear cell histology (see Fig. e161-4).[15]

With the single agent success of immunotherapy and the favorable adverse drug reaction profile, immunotherapy combined with TKIs offer improved clinical response rates and overall survival benefits in the first-line setting for mRCC. Four TKI + immunotherapy regimens are recommended in the first-line mRCC setting: axitinib plus pembrolizumab (PD-1),[59] axitinib plus avelumab (PD-L1),[60] cabozantinib plus nivolumab (PD-1),[61] and lenvatinib plus pembrolizumab.[62]

Axitinib can be combined with either pembrolizumab or avelumab for the first-line treatment of mRCC.[59,60] Axitinib plus pembrolizumab has a median progression-free survival of 15 months, an objective response rate of 60%, and an improvement in overall survival over single agent TKI in the first-line setting. The benefit of this combination treatment is observed across the three IMDC risk groups and regardless of PD-L1 expression. Grade 3 or higher treatment-related adverse drug reactions occurred in 63% of the patients and 20% required a dose reduction to axitinib.[59]

Axitinib plus avelumab has resulted in a median progression-free survival of 13.3 months and an objective response rate of 53%.[60] However overall survival results are immature and currently limiting adoption of this regimen in the first-line setting. PD-L1 expression levels do not impact progression-free survival or objective response rates. Grade 3 or higher treatment-related adverse drug reactions occurred in 57% of the patients treated with avelumab plus axitinib group and 42% of patients required a dose reduction to axitinib.[60] Based on these data, the combination of pembrolizumab plus axitinib received FDA approval in April 2019 for first-line treatment of advanced RCC, and the combination of avelumab plus axitinib received FDA approval in May 2019 for first-line treatment of advanced RCC. As a result, pembrolizumab plus axitinib is preferred first-line treatment regimen by NCCN for metastatic clear cell RCC patients across risk categories, as well as a second-line treatment option for all patients with clear cell mRCC (see Fig. e161-4).[15] Avelumab plus axitinib is recommended by NCCN as a first-line option for mRCC with clear cell histology across risk categories.[15]

The combination of nivolumab plus cabozantinib is an additional treatment option in the first-line setting.[61] This combination resulted in a median progression free-survival of 16.6 months, overall survival was significantly improved compared a single agent TKI (sunitinib), and the objective response rate was 56%. Grade 3 or higher treatment related adverse events occurred in 61% of patients with 56% of patients requiring a dose reduction to cabozantinib.[61] In January 2021, the FDA approved the combination of cabozantinib and nivolumab as first-line treatment for patients with advanced RCC.

Lastly, the combination of lenvatinib plus pembrolizumab has resulted in not only the longest progression-free survival estimates (23.9 months) and objective response rates (71%) in the first-line setting of any TKI/immunotherapy combination but also the highest rate of grade 3 adverse drug reactions (72%) and percentage of patients requiring a dose reduction to the TKI (69%).[62] This combination improved overall survival compared to single agent TKI. The combination of lenvatinib plus pembrolizumab was FDA approved for the first-line mRCC population in August 2021. Taken together, both cabozantinib plus nivolumab and lenvatinib plus pembrolizumab are included as preferred first-line NCCN treatment options for clear cell, mRCC across risk groups.[15]

In summary, immunotherapy (PD-1, PD-L1, and CTLA-4 inhibitors) is an integral component of the management of patients with advanced mRCC either as single agents or in combination. PD-L1 expression does not have predictive value in mRCC. Individual patient characteristics, goal of therapy, and adverse event profile and expected tolerability of these immunotherapy combinations can inform treatment selection.

Targeted Therapy

⑧ ⑨ Targeted agents are a cornerstone of first- or second-line therapy for the treatment of advanced RCC or mRCC (see Table e161-4 and Fig. e161-4).

TABLE e161-4

Comparison and Dosing of Targeted Agents for Patients with mRCC*

Targeted Agent	Dose and Administration	Special Population Dose	Drug Interactions
VEGF-TKIs			
Axitinib[8]	5 mg orally twice daily (may take with or without food) Maintenance Dose: Increase every 2 weeks to 7 mg orally twice daily and then 10 mg orally twice daily	Hepatic impairment (Childs–Pugh class B), reduce dose by half	CYP3A4/5 inhibitors may increase exposure; reduce dose of axitinib by half if a strong CYP3A4/5 inhibitor is administered CYP3A4/5 inducers may decrease exposure
Cabozantinib[9]	60 mg orally daily (take on an	Mild-to-moderate hepatic impairment, 40 mg orally daily Do not use in severe hepatic impairment	CYP3A4 inducers may decrease cabozantinib

	empty stomach) 40 mg orally once daily (take on an empty stomach) in combination with nivolumab		exposure CYP3A4 inhibitors may increase cabozantinib exposure
Lenvatinib[11]	18 mg orally daily (take with or without food) in combination with everolimus 20 mg orally daily (take with or without food) in combination with pembrolizumab	Severe renal impairment (CrCl <30 mL/min [0.5 mL/s]), 10 mg orally daily Severe hepatic impairment (Childs–Pugh Class C), 10 mg orally once daily	CYP3A4 and Pgp inducers may decrease lenvatinib exposure CYP3A4, Pgp, and BCRP inhibitors may increase lenvatinib exposure
Pazopanib[5]	800 mg orally daily (take on an empty stomach)	Moderate hepatic impairment, 200 mg orally once a day. Do not use in severe hepatic impairment	CYP3A4 inducers may decrease pazopanib exposure CYP3A4 inhibitors may increase pazopanib exposure
Sorafenib[7]	400 mg orally twice daily	No data	UGT1A1 and UGT1A9 substrates may have increased exposure when coadministered with sorafenib because of inhibition of glucuronidation CYP3A4 inducers may decrease sorafenib exposure
Sunitinib[6]	50 mg orally daily × 4 weeks; then off 2 weeks (may take with or without food)	Hemodialysis: no adjustment to starting dose; subsequent doses may be increased up to two-fold	CYP3A4 inducers may decrease sunitinib exposure CYP3A4 inhibitors may increase sunitinib exposure
Tivozanib[10]	1.34 mg orally daily	Moderate hepatic impairment (total bilirubin > 1.5-3 x upper limit of normal with any AST), 0.89 mg orally once daily for 21 days on	Strong CYP3A inducers may decrease tivozanib

		treatment followed by 7 days off treatment for a 28-day cycle. Dose has not been established for severe hepatic impairment (total bilirubin > 3-10 x upper limit of normal with any AST)	exposure
VEGF Inhibitor Monoclonal Antibody			
Bevacizumab[3]	10 mg/kg IV every 2 weeks	No data	No known drug interactions
mTOR inhibitors			
Everolimus[4]	10 mg orally daily 5 mg orally daily in combination with lenvatinib	Hepatic impairment (Childs–Pugh class B), reduce dose to 5 mg orally daily	CYP3A4 and Pgp inhibitors may increase everolimus exposure CYP3A4 inducers may decrease everolimus exposure
Temsirolimus[2]	25 mg IV once weekly	If mild hepatic impairment, reduce dose to 15 mg IV once weekly. Do not use if bilirubin is greater than 1.5 times the ULN	CYP3A4 inhibitors may increase temsirolimus exposure CYP3A4 inducers may decrease temsirolimus exposure

BCRP, breast-cancer resistance protein; CrCl, creatinine clearance; CYP, cytochrome P450; UGT, uridine 5'-diphospho-glucuronosyltransferase; ULN, upper limit of normal; VEGFA, vascular endothelial growth factor A.

Sunitinib

Sunitinib is an orally administered antiangiogenic agent that inhibits multiple tyrosine kinases, including the three VEGFRs and PDGFR.[63] It is usually administered in a 6-week cycle at 50 mg given orally daily for 4 weeks followed by 2 weeks without treatment. Sunitinib efficacy in the first-line setting has been evaluated across several clinical trials. In the first-line setting, the median progression-free survival is approximately 8.3 months to 12.3 months among all risk groups and 5.6 to 8.4 months in intermediate- and poor-risk groups.[6,57,59–62,64] The median progression free survival is approximately 8.3 months when used as a subsequent-line treatment after cytokine therapy.[65] Sunitinib is associated with diarrhea, vomiting, hypertension, hand–foot syndrome, hair discoloration, and myelosuppression. Most adverse drug reactions can be managed through supportive care and/or dose modifications. Sunitinib is recommended as an optional first-line treatment of mRCC in patients with clear cell histology and for second-line treatment of mRCC (see Fig. e161-4).[15]

Sorafenib

Sorafenib is another orally administered antiangiogenic agent that inhibits multiple tyrosine kinases, including the three VEGFRs, PDGFRβ, v-Raf murine sarcoma viral oncogene homolog 1, or Raf-1, v-Raf murine sarcoma viral oncogene homolog B, or BRAF, fms-like tyrosine kinase receptor-3, or FLT-3, fibroblast growth factor receptor-1 (FGFR1), and mast/stem cell growth factor receptor (c-KIT). Sorafenib is approved by the FDA for the second-line treatment of advanced or mRCC after progression on cytokine therapy at a dose of 400 mg orally twice daily. The median progression-free survival observed in patients treated with sorafenib was 5.5 months.[7] The median progression free survival was 4.7 months in patients treated with prior VEGF-targeted therapy.[7] Sorafenib is generally well tolerated with few grade 3 or 4 adverse drug reactions, although almost 5% of patients reported cardiac infarct or ischemic events.[7] Sorafenib is associated with diarrhea, nausea, vomiting, weight loss, fatigue, hand–foot syndrome, desquamating rash, hypertension, cardiac ischemia, and hemorrhagic events.[7] Sorafenib is recommended by NCCN as a second-line option for patients with mRCC (see Fig. e161-4).[15]

Pazopanib

Pazopanib is an orally administered multikinase inhibitor that is FDA approved for the treatment of mRCC. The starting dose for pazopanib is 800 mg orally once daily. Pazopanib inhibits multiple receptors, including the three VEGFRs, PDGFRα and, βFGFRs, c-KIT, interleukin-2 receptor inducible T-cell kinase, and leukocyte-specific protein tyrosine kinase.[66] Pazopanib was evaluated in a phase III clinical trial in both treatment-naïve and cytokine-pretreated patients with mRCC.[5] The overall study population had a median progression-free survival of 9.2 months. Treatment-naïve patients experienced a median progression-free survival of 11.1 months. Pazopanib was generally well tolerated, with few grade 3 or 4 adverse drug reactions.[5] A phase III noninferiority trial compared the efficacy of pazopanib versus sunitinib as first-line treatment in previously untreated patients with clear cell mRCC.[64] The progression-free survival with pazopanib was noninferior to sunitinib (8.4 months vs 9.5 months, respectively). Patients treated with sunitinib experienced a higher incidence of fatigue (63% vs 55%), hand–foot syndrome (50% vs 29%), and thrombocytopenia (78% vs 41%). Conversely, patients treated with pazopanib had a higher incidence of elevated LFTs (60% vs 43%). Quality-of-life measures, particularly those related to fatigue or soreness in the hands, feet, mouth, and/or throat, favored pazopanib. Investigators on this phase III trial concluded that pazopanib and sunitinib have similar efficacy in the first-line setting, but safety and quality-of-life profiles favor pazopanib.[64] A phase II trial had a progression-free survival for pazopanib of 7.5 months in the second-line setting following prior VEGF-targeted therapy.[67] Pazopanib is associated with transaminitis, myelosuppression, diarrhea, nausea, vomiting, fatigue, hypertension, hair discoloration, hemorrhagic events, thromboembolism, and hypothyroidism.[5] Pazopanib is recommended by NCCN as a first-line option for patients with mRCC clear cell and a second-line option for patients with mRCC (see Fig. e161-4).[15]

Axitinib

Axitinib is a second-generation orally administered multikinase inhibitor that is FDA approved for the treatment of advanced RCC after progression on one prior systemic therapy. The starting dose for axitinib is 5 mg orally twice daily and may be titrated at 2-week intervals to 7 mg twice daily and then 10 mg twice daily, if well tolerated. Axitinib is a second-generation, selective inhibitor of all three VEGFRs, and is 50 to 450 times more potent than first-generation VEGFR inhibitors (eg, sorafenib and sunitinib). Unlike first-generation agents, axitinib has limited activity beyond VEGFR blockade, which potentially results in reduced off-target adverse drug reactions.[68] Axitinib was compared to sorafenib in a phase III trial in patients with clear cell RCC who had progressed on prior therapy. The trial had a progression-free survival benefit in patients treated with axitinib when compared to patients treated with sorafenib (6.7 vs 4.7 months). The most common adverse drug reactions seen with axitinib were diarrhea, hypertension, fatigue, nausea, and dysphonia, and patients had notably less hand–foot syndrome and alopecia compared with those treated with sorafenib.[8] A second phase III trial was conducted to assess the benefit of axitinib as a first-line treatment. This open-label trial randomized patients to receive either axitinib or sorafenib. Progression-free survival was not significantly improved with axitinib compared with sorafenib. Despite the lack of a significant difference in progression-free survival between the two treatment arms, there was sufficient evidence of axitinib activity and an acceptable adverse drug reaction profile in the first-line setting.[69] Based on the results from these two phase III trials, single-agent axitinib is an option for the first-line treatment of mRCC in patients with clear cell histology and as a second-line treatment option (see Fig. e161-4).[15]

Cabozantinib

Cabozantinib is FDA approved for the treatment of advanced RCC. The starting dose for cabozantinib monotherapy is 60 mg orally once daily in the tablet formulation (Cabometyx). The cabozantinib tablet formulation (Cabometyx) is not interchangeable with the cabozantinib capsule formulation (Cometriq) due to lack of bioequivalence.[70] Cabozantinib potently inhibit VEGFR2, as well as MET, FLT-3, Ret proto-oncogene (RET), and AXL receptor tyrosine kinase.[71] The phase II CABOSUN trial compared cabozantinib with sunitinib in patients with mRCC who had not received any prior systemic treatments and who had intermediate- or poor-risk disease based on the IMDC prognostic criteria. Treatment with cabozantinib was associated with a median progression-free survival of 8.2 months.[72]

The phase III METEOR trial compared oral cabozantinib with everolimus in patients with mRCC who had failed at least one previous therapy with a TKI. Cabozantinib was associated with a median progression free survival of 7.4 months.[9] Cabozantinib-related adverse drug reactions are similar to other approved VEGF-pathway inhibitors, and include fatigue, diarrhea, nausea, proteinuria, decreased appetite, palmar-plantar erythrodysesthesia and vomiting.[9] According to NCCN, cabozantinib is a first-line treatment option for patients with mRCC clear cell histology and intermediate- or poor-risk disease and for patients with mRCC clear cell histology and favorable-risk disease (see Fig. e161-4). Additionally, cabozantinib is a second-line treatment option in mRCC.[15]

Lenvatinib

Lenvatinib is another multitargeted TKI that inhibits VEGFRs, FGFRs, PDGFRα, RET, and c-KIT. Lenvatinib, in combination with everolimus, is FDA approved for the treatment of mRCC after failure of one prior anti-angiogenic therapy. The lenvatinib starting dose is 18 mg orally once daily when used in combination with everolimus. Approval was based on a phase II trial that compared the combination of lenvatinib plus everolimus to everolimus alone or lenvatinib alone. The median progression-free survival was 14.6 months for lenvatinib plus everolimus.[11] Combination lenvatinib plus everolimus is an appropriate second-line treatment option for mRCC (see Fig. e161-4).[15]

Tivozanib

Tivozanib is a multikinase inhibitor that inhibits VEGFR-1, VEGFR-2, VEGFR-3, c-KIT and PDGFR β.[73] Tivozanib is FDA approved for the treatment of relapsed or refractory advanced RCC following two or more prior systemic treatments. Tivozanib is administered at a starting dose of 1.34 mg orally once daily on days 1 through 21 of a 28-day cycle. The FDA approval was based on the results from a phase III trial (TIVO-3) evaluating tivozanib versus sorafenib in patients with advanced RCC following 2 or 3 prior systemic therapies. Median progression-free survival was 5.6 months with tivozanib.[10] Most common adverse events with tivozanib include hypertension, diarrhea, fatigue, decreased appetite, dysphonia, nausea, hypothyroidism, cough and stomatitis.[73] Tivozanib is recommended by NCCN as an option for subsequent line therapy in advanced RCC patients who have received two or more prior systemic therapies (see Fig. e161-4).[15]

Bevacizumab

Bevacizumab is a humanized monoclonal antibody that binds circulating VEGFA, and inhibits the ligand from binding to the VEGFRs.[63] Bevacizumab infusion at a dose of 10 mg/kg IV every 2 weeks was evaluated in a phase III trial in patients who received prior cytokine therapy.[3] The median progression free survival was 4.8 months. The most common adverse events observed in patients treated with bevacizumab were hypertension, epistaxis, malaise, hematuria, and asymptomatic proteinuria.[3] Bevacizumab monotherapy is also an option as second-line therapy (see Fig. e161-4).[15]

Temsirolimus

Temsirolimus is an intravenously administered mTOR inhibitor indicated for first-line treatment of patients with poor-risk mRCC. Temsirolimus is administered at a dose of 25 mg as an IV infusion once weekly. As discussed previously, mTOR is a downstream component of the PI3K/AKT pathway that ultimately results in HIF regulation.[28,30] Temsirolimus was compared with interferon alpha or the combination of the two agents in a phase III trial of treatment-naive patients with higher risk mRCC. About 75% of patients were poor-risk and 25% of the patients were intermediate-risk. The trial was discontinued early, after the second interim analysis, based on temsirolimus benefit.[2] The median overall survival was 10.9 months in patients who received single-agent temsirolimus. Median progression-free survival for temsirolimus 5.5 months. Patients receiving temsirolimus were more likely to experience hyperlipidemia, hyperglycemia, and hypercholesterolemia, which were expected adverse drug reactions based on mTOR's role in the regulation of glucose and lipid metabolism. The results of this trial support the use of temsirolimus for first-line treatment of patients with poor-risk prognostic features.[74–76] Based on these results, temsirolimus is recommended by NCCN for first-line treatment in patients with mRCC with clear cell histology and poor-risk disease (see Fig. e161-4). It is also a second-line option in patients with mRCC.[15]

Everolimus

Everolimus is an orally administered mTOR inhibitor, which is approved by the FDA for patients with advanced RCC who had failed sorafenib or sunitinib therapy. Everolimus monotherapy is administered at a dose of 10 mg orally once daily. When everolimus is used in combination with lenvatinib, the dose is 5 mg orally once daily.[77] A phase III trial randomized patients who had failed previous sunitinib or sorafenib therapy to everolimus or placebo.[4] The trial had a median progression-free survival of 4 months in patients treated with everolimus. All medication-related adverse drug reactions occurred more frequently in the everolimus group than in the placebo group, but severe adverse drug reactions were uncommon. Elevations in glucose and lipids were seen because of everolimus's ability to inhibit mTOR.[78] The use of everolimus as monotherapy has decreased given its approval in combination with lenvatinib for the treatment of mRCC in the second line and beyond (see discussion above), but current NCCN guidelines include single-agent everolimus as an option in this setting (see Fig. e161-4).[15]

Summary of Targeted Therapies

Although sunitinib, sorafenib, pazopanib, axitinib, cabozantinib, and lenvatinib are all orally administered antiangiogenic multikinase inhibitors, these agents have different efficacy and adverse drug reaction profiles (see Tables e161-4 and e161-5).

TABLE e161-5

Drug Monitoring Recommendations for Targeted Agents Used in Metastatic RCC*

Targeted Agent	Adverse Drug Reactions	Monitoring Parameters	Comments
VEGFR TKIs			
Axitinib[8]	Diarrhea, hypertension, fatigue, decreased appetite, nausea, dysphonia, hand–foot syndrome, weight loss, vomiting, asthenia, constipation, hypothyroidism, stomatitis, arthralgia, proteinuria, rash, dry skin, headache, dyspepsia, cough Laboratory abnormalities: anemia, lymphopenia, thrombocytopenia, hyperkalemia, hyperglycemia, hypocalcemia, decreased bicarbonate, increased lipase, amylase, SCr, and LFTs	Blood pressure, VTE, hemorrhage, GI perforation or fistula, thyroid function, wound healing, RPLS, proteinuria, LFTs, pregnancy	Withhold axitinib at least two days prior to surgery. Do not resume axitinib for at least 2 weeks following major surgery and adequate wound healing.
Cabozantinib[9]	Diarrhea, fatigue, nausea, decreased appetite, hypertension, hand–foot syndrome, stomatitis, dysgeusia, rash, dysphonia, proteinuria, increased LFTs, hypertriglyceridemia, hyperglycemia, electrolyte abnormalities, venous thromboembolism, delayed wound healing	CBC, electrolytes, LFTs, urinalysis, blood pressure, ECG, monitor for VTE or hemorrhagic events	Withhold cabozantinib at least 3 weeks prior to surgery, including dental surgery. Do not resume cabozantinib for at least 2 weeks following major surgery and adequate wound healing. Do not administer to a patient at risk of severe hemorrhage.
Lenvatinib[11]	Diarrhea, fatigue, decreased appetite, hypertension, edema, stomatitis, nausea, vomiting, arthralgias/myalgias, hemorrhagic events, rash, proteinuria, QTc interval	Renal function, electrolytes, LFTs, urinalysis, blood pressure, ECG, monitor for VTE or hemorrhagic events	Withhold lenvatinib at least 1 week prior to surgery. Do not resume lenvatinib for at least 2 weeks following major surgery

	prolongation, delayed wound healing, thromboembolic events, hypocalcemia		and adequate wound healing.
Pazopanib[5]	Elevated ALT, leukopenia, thrombocytopenia, diarrhea, nausea, vomiting, hypertension, hair discoloration, QTc interval prolongation, hemorrhage, thromboembolism, hypothyroidism	LFTs, electrolytes, thyroid function, urinalysis, ECG, blood pressure	Withhold pazopanib at least 1 week prior to surgery. Do not resume pazopanib for at least 2 weeks following major surgery and adequate wound healing.
Sorafenib[7]	Diarrhea, nausea, vomiting, anorexia, fatigue, hand–foot syndrome, desquamating rash, hypertension, cardiac ischemia, hemorrhagic events	Electrolytes, blood pressure, LFTs, ECG for QTc interval prolongation in patients with CHF, bradyarrhythmia, or electrolyte abnormalities	Withhold sorafenib at least 10 days prior to surgery. Do not resume sorafenib for at least 2 weeks following major surgery and adequate wound healing. Consider discontinuing therapy if clinical manifestations of cardiac ischemia or hemorrhagic event occur.
Sunitinib[6]	Leukopenia, thrombocytopenia, diarrhea, nausea, vomiting, anorexia, constipation, mucositis, hypertension, hand–foot syndrome, hair discoloration, hypothyroidism, decreased LVEF	Adrenal insufficiency, CBC with platelets, electrolytes, LFTs, thyroid function, urinalysis, blood pressure, ECG, for hemorrhagic events, for signs and symptoms of CHF or TLS	Withhold sunitinib at least 3 weeks prior to surgery. Do not resume sunitinib for at least 2 weeks following major surgery and adequate wound healing. Discontinue sunitinib if clinical manifestations of CHF occur. Delay or reduce dose if no clinical manifestations of CHF but EF <50% (0.5) and >20% (0.2) below baseline.
Tivozanib[10]	Hypertension, diarrhea, fatigue, decreased appetite, dysphonia, nausea, hypothyroidism, cough and stomatitis	Blood pressure, proteinuria, thyroid dysfunction, RPLS, monitor for cardiac failure, cardiac ischemia, arterial and venous thromboembolic events, hemorrhagic events, wound healing, pregnancy	Withhold tivozanib 24 days prior to surgery. Do not resume tivozanib for at least 2 weeks after major surgery and adequate wound healing.
Monoclonal Antibody and VEGFA Inhibitor			
Bevacizumab[3]	Epistaxis, delayed wound healing, hypertension, thromboembolic events, proteinuria, GI perforation	Blood pressure, urine protein	Withhold bevacizumab for at least 28 days prior to surgery. Do not resume bevacizumab within 28 days after major surgery and adequate wound healing.

mTOR Inhibitors			
Everolimus[4]	Abdominal pain, asthenia, cough, dehydration, diarrhea, dyspnea, fatigue, infections, pneumonitis, and stomatitis Laboratory abnormalities: anemia, hypercholesterolemia, hypertriglyceridemia, hyperglycemia, lymphopenia, and increased SCr	Blood glucose, serum cholesterol, SCr, triglycerides, LFTs, electrolytes, and CBC	Withhold everolimus for at least 1 week prior to surgery. Do not resume everolimus for at least 2 weeks after major surgery and adequate wound healing. Avoid live vaccinations and close contact with those who receive live vaccines.
Temsirolimus[2]	Anorexia, asthenia, edema, hypersensitivity reactions, infections, interstitial lung disease, mucositis, nausea, rash, wound healing complications Laboratory abnormalities: anemia, hyperglycemia, hyperlipidemia, hypertriglyceridemia, hypophosphatemia, leukopenia, lymphopenia, thrombocytopenia, and increased LFTs or SCr	Blood glucose, serum cholesterol, SCr, triglycerides, LFTs, electrolytes, and CBC	Caution surgery and abnormal wound healing if administered within a few weeks starting treatment with temsirolimus or during temsirolimus therapy. Avoid live vaccinations and close contact with those who received live vaccines.

ALT, alanine aminotransferase; CHF, congestive heart failure; ECG, electrocardiogram; EF, ejection fraction; GI, gastrointestinal; LVEF, left ventricular ejection fraction; RPLS, reversible posterior leukoencephalopathy syndrome; SCr, serum creatinine; TLS, tumor lysis syndrome; VTE, venous thromboembolism.

Sunitinib, pazopanib, axitinib, and cabozantinib have been reported to improve progression-free survival in both first- and second-line treatment settings, but sorafenib has improved progression-free survival only in the second-line treatment setting. Lenvatinib is only approved in combination with everolimus in patients who have failed other anti-angiogenic therapy. Tivozanib is approved in the subsequent line setting after two or more prior systemic therapies. In addition to differences in efficacy, these agents have differences in their adverse drug reaction profiles. Sunitinib and pazopanib are associated with higher rates of hypertension and hair discoloration than sorafenib or cabozantinib. Sunitinib is also associated with higher rates of hypothyroidism than sorafenib. Sorafenib is associated with higher rates of gastrointestinal adverse drug reactions and hand–foot syndrome than sunitinib and pazopanib. Sunitinib and tivozanib are administered cyclically. Sunitinib is given intermittently during a 6-week cycle (4 weeks on treatment, 2 weeks off treatment), and tivozanib is administered on a 28-day cycle (21 days on treatment, 7 days off treatment). Sorafenib, pazopanib, cabozantinib, and lenvatinib are administered continuously.

Similar comparisons can be drawn between temsirolimus and everolimus, both of which are mTOR inhibitors, but the two drugs still have a few important differences. First, everolimus is administered orally once daily, whereas temsirolimus is administered as a once weekly intravenous infusion. Temsirolimus was studied in the first-line setting in poor-risk patients, while everolimus was studied in the second-line setting in patients who had progressed after sorafenib or sunitinib.

EVALUATION OF THERAPEUTIC OUTCOMES

The outcome of treatment in patients with RCC depends on the disease stage at the time of diagnosis. Whereas localized RCC has a five-year relative survival of about 93%, mRCC has a five-year survival of less than 14%.[13] The standard-of-care in patients with localized RCC (stage I-III) is surgical resection of the tumor, with a goal of long-term survival and cure. However, 20% to 30% of patients will relapse within three years, and 50% to 60% of these patients will have distant recurrence to the lungs. The NCCN Kidney Cancer guidelines recommend that patients undergo a medical history; physical examination; comprehensive metabolic panel (including blood urea nitrogen, SCr, calcium levels, and LFTs); and abdominal, pelvic, and chest imaging every 6 months for the first two years after surgery and annually thereafter.[15] For patients with stage IV and unresectable RCC, the goal of treatment is to control disease burden and prolong survival while maximizing quality of life.

Current treatment options depend on RCC histology, comorbidities, patient performance status, and prognosis risk group, and include enrollment in a clinical trial. The preferred first-line regimens for patients with favorable risk clear cell mRCC include axitinib plus pembrolizumab, cabozantinib plus nivolumab, and lenvatinib plus pembrolizumab.[15] The preferred first-line regimens for patients with intermediate- or poor-risk clear cell mRCC include axitinib plus pembrolizumab, cabozantinib plus nivolumab, ipilimumab plus nivolumab, lenvatinib plus pembrolizumab, and cabozantinib.[15] If a patient has disease progression on the initial treatment regimen, preferred subsequent treatment options include cabozantinib, lenvatinib plus everolimus, and nivolumab.[15] At each patient visit, adherence to orally administered targeted therapy regimens must be strongly emphasized, and treatment-related adverse drug reactions should be closely monitored. Because optimizing quality of life is an important therapeutic endpoint in mRCC, best supportive care should be given to all patients, which may include palliative radiation, metastectomy, and bisphosphonates or receptor activator of nuclear factor-κB ligand, or RANKL, inhibitors for the treatment of bone metastases.[15]

CONCLUSION

Renal cell carcinoma is the most frequent malignancy of the kidney and renal pelvis. Clear cell carcinoma is the most predominate histologic subtype characterized by inactivation of the *VHL* gene resulting in increased production of proangiogenic growth factors. Drug therapies targeting these growth factors play a critical role in the management of advanced disease. Immunotherapy is another integral component of drug treatment for mRCC either as single agents or combined with TKIs. Individual patient characteristics, goal of therapy, and expected tolerability of drug therapy informs treatment selection.

ABBREVIATIONS

AJCC	American Joint Committee on Cancer
AKT	protein kinase B
BMI	body mass index
CBC	complete blood count
c-KIT	mast/stem cell growth factor receptor (or CD117)
CT	computed tomography
CTLA-4	cytotoxic T lymphocyte-associated antigen-4
DNA	deoxyribonucleic acid
FDA	Food and Drug Administration
FH	fumarate hydratase
HR	hazard ratio
HIF	hypoxia-inducible factor

IMDC	International Metastatic Renal Cell Carcinoma Database Consortium
LDH	lactate dehydrogenase
LFT	liver function test
MDR1	multidrug resistance gene 1
MET	mesenchymal–epithelial transition
mRCC	metastatic renal cell carcinoma
MRI	magnetic resonance imaging
MSKCC	Memorial Sloan-Kettering Cancer Center
mTOR	mammalian target of rapamycin
NCCN	National Comprehensive Cancer Network
PD-1	programmed cell death protein-1
PD-L1	programmed death-ligand 1
PDGF	platelet-derived growth factor
PDGFR	platelet-derived growth factor receptor
PET	positron emission tomography
Pgp	P-glycoprotein
PI3K	phosphatidylinositol 3-kinase
pVHL	von Hippel-Lindau protein
RCC	renal cell carcinoma
RET	Ret proto-oncogene
SCr	serum creatinine
TGF	transforming growth factor
TKI	tyrosine kinase inhibitor
TNM	tumor, lymph node, metastasis
VEGF	vascular endothelial growth factor
VEGFA	vascular endothelial growth factor A

VEGFR	vascular endothelial growth factor receptor
VHL	von Hippel-Lindau

SELF ASSESSMENT QUESTIONS

1. Which of the following statements about the epidemiology of RCC is TRUE?
   - A. RCC is more common in men than in women.
   - B. RCC is more common in pediatric patients and young adults compared to older adults.
   - C. RCC is more common in underdeveloped countries.
   - D. The incidence of RCC has decreased over the past three decades.
2. Which of the following is the most established risk factor for the development of renal cell carcinoma?
   - A. Smoking
   - B. Hypertension
   - C. Chronic kidney disease

   D. Obesity

3. Which of the following statements about the subtypes of renal cell carcinoma is TRUE?

   A. Clear cell carcinoma is the most common histological subtype, and the hallmark of the disease is mutations in the MET oncogene.

   B. Clear cell carcinoma typically affects the proximal tubule of the kidney and is more likely to metastasize than other subtypes.

   C. Papillary subtypes are further divided into types 1 and 2 and have a less favorable prognosis than clear cell subtype.

   D. Oncocytoma subtypes are aggressive and commonly metastasize, as they are due to mutations in the VHL tumor suppressor gene.

4. Inactivation of the VHL protein (pVHL) is commonly seen in renal cell carcinoma. Which of the following statements accurately describes the role of inactivation of pVHL in oncogenesis?

   A. pVHL is involved in the recognition of cells by the immune system, and its inactivation leads to immune evasion by the developing tumor.

   B. pVHL regulates cellular response to oxygen. Its inactivation leads to the accumulation of hypoxia-inducible factors, that enable tumor cells to adapt and survive hypoxic insult.

   C. pVHL regulates the cell cycle. Its inactivation leads to unchecked cell division and avoidance of apoptosis.

   D. pVHL is expressed primarily in the kidneys and is essential to renal function. Inactivation leads to chronic kidney disease, and eventually the development of cancer.

5. Which of the following is most consistent with the clinical presentation of early stage renal cell carcinoma?

   A. Hematuria, flank pain, and adenopathy

   B. Anemia and cough

   C. Urinary retention and bone pain

   D. Asymptomatic (no new symptoms)

6. Which of the following patients with renal cell carcinoma who are in need of systemic therapy would you classify as intermediate risk based on the IMDC Criteria?

   A. A 52-year-old man who was diagnosed two years ago has a Karnofsky performance status of 100%, calcium 8.7 mg/dL (2.18 mmol/L), and a normal CBC.

   B. A 72-year-old woman who was diagnosed 6 months ago has a Karnofsky performance status of 70%, calcium 11.1 mg/dL (2.78 mmol/L), and a normal CBC.

   C. A 65-year-old man who was diagnosed five years ago has a Karnofsky performance status of 90%, calcium 9.0 mg/dL (2.25 mmol/L), platelet 40,000/μL (40 × 10^9/L), and otherwise normal CBC.

   D. A 60-year-old man who was diagnosed 6 months ago has a Karnofsky performance status of 100%, calcium 8.9 mg/dL (2.23 mmol/L), hemoglobin 11.0 g/dL (110 g/L; 6.83 mmol/L), and otherwise normal CBC.

7. For which of the following stages of renal cell carcinoma is surgery a treatment option?

   A. Stage II

   B. Stage III

   C. Stage IV

   D. All stages of the disease

8. Tivozanib is a multikinase inhibitor that is recommend for use in which of the following setting?

   A. After surgical resection in early-stage RCC

   B. Prior to surgical resection in early-stage RCC

   C. First- or second-line treatment for advanced RCC

   D. After two or more lines of systemic treatment for advanced RCC

9. Which of the following is TRUE about immune checkpoint inhibitors used in the treatment of renal cell carcinoma?

   A. PD-1 inhibitors act in the T-cell priming phase in the lymph node, while CTLA-4 inhibitors act at the T-cell effector phase in the peripheral tissue.

   B. PD-1 inhibitors generally have a more manageable adverse drug reaction profile compared with CTLA-4 inhibitors.

   C. PD-1 inhibitors and CTLA-4 inhibitors cannot be used in combination due to intolerable adverse drug reactions.

   D. CTLA-4 inhibitors alone are preferred for the treatment of RCC due to their superior activation of the immune response.

10. Which of the following oral agents used in the treatment of renal cell carcinoma is correctly matched with its mechanism of action?

   A. Everolimus: selective TKI of pVHL

   B. Sorafenib: selective TKI that inhibits multiple VEGFRs

   C. Lenvatinib: multikinase inhibitor of VEGFR, FGFR, PDFR, RET, and c-KIT

   D. Sunitinib: mTOR inhibitor

11. Hypertension, fatigue, and diarrhea are treatment-induced adverse drug reactions most likely related to which of the following pharmacotherapeutics options?

   A. Nivolumab

   B. Cabozantinib

   C. Ipilimumab

   D. Everolimus

12. Which of the following regimens would be appropriate for first-line treatment of favorable-risk clear cell metastatic renal cell carcinoma?

   A. Temsirolimus

   B. Ipilimumab plus nivolumab

   C. Lenvatinib plus pembrolizumab

   D. Interferon alpha

13. Patients with poor-risk metastatic renal cell carcinoma should be treated with which of the following regimens based on an overall survival benefit?

   A. Everolimus

B. Ipilimumab plus nivolumab

C. Pazopanib

D. Interferon alpha

14. Patients with metastatic renal cell carcinoma who have progressed on first-line ipilimumab plus nivolumab should be treated with which of the following regimens based on a category 1 recommendation from the NCCN guidelines?

A. Cabozantinib

B. Nivolumab

C. Sorafenib

D. High-dose interleukin-2

15. Which of the following may be considered overlapping adverse drug reactions and be attributed to both lenvatinib and pembrolizumab?

A. Pneumonitis, diarrhea, and hypertension

B. Diarrhea, hypothyroidism, and transaminitis (increased liver function tests)

C. Palmar-plantar erythrodysesthesia (hand–foot syndrome), transaminitis (increased liver function tests), and pneumonitis

D. Diarrhea, palmar-plantar erythrodysesthesia (hand–foot syndrome), and hypertension

SELF ASSESSMENT QUESTIONS-ANSWERS

1. **A.** See section "Epidemiology." RCC is the sixth most common cancer in men and the ninth most common cancer in women. It is more common in developed countries (such as Europe and North American) and more common in older patients (median age of diagnosis is 64 years old). The incidence of RCC has increased over the past three decades, perhaps due to the increased use of imaging techniques such as CT or PET scans.

2. **A.** See section "ETIOLOGY." Smoking remains the most consistently established risk factor and is responsible for 10% to 30% of RCC diagnoses. Hypertension and obesity are risk factors for the development of RCC, but not to the extent of smoking. Chronic kidney disease has not been established as a risk factor for RCC (although it is often associated with other risk factors, such as hypertension).

3. **B.** See section "Subtypes and Pathophysiology." Clear cell carcinoma is the most common subtype of RCC but the hallmark of the disease is inactivation of the *VHL* gene (*MET* mutations are more commonly associated with the hereditary papillary subtype 1 tumors). Clear cell RCC commonly affects the proximal tubule (as does the papillary subtype) but is more likely to metastasize than the papillary subtype. Oncocytoma subtypes are most often benign, and hereditary forms are often associated with mutations in the *BHD* gene.

4. **B.** See section "Subtypes and Pathophysiology" on clear cell histology. Figures e161-1 and e161-2 show the role of inactivation of pVHL in the development of a tumor.

5. **D.** See section "Diagnosis." Early stage RCC often presents with the patient not recognizing any new symptoms, and these tumors are often caught during routine imaging for other medical issues. The presence of adenopathy, anemia, cough, and bone pain would all be suggestive of metastatic disease, with tumors in areas other than the kidney (ie, lymph nodes, lungs, bones).

6. **D.** See Table e161-3 for the IMDC Criteria. Patients with one to two prognostic factors are considered intermediate-risk. Patient A has zero factors (low/favorable-risk), patient B has three factors (high-risk), patient C has zero factors (low-risk), and patient D has two factors (intermediate-risk).

7. **D.** See subsection "Surgery" under "Treatment." Surgery is an option in all stages of RCC, including those with metastatic disease, especially if they have a low disease burden.

8. **D**. See subsection “Targeted Therapy-Tivozanib” under “Treatment.” Tivozanib is recommended by NCCN and FDA approved as an option for subsequent-line therapy in advanced RCC patients who have received two or more prior systemic therapies.

9. **B.** See subsection “Immunotherapy” under “Treatment.” PD-1 inhibitors act in the T-cell effector phase in the peripheral tissue and therefore have a more manageable adverse drug reaction profile compared to CTLA-4 inhibitors. PD-1 inhibitors can be used in combination with CTLA-4 inhibitors (such is the case with ipilimumab and nivolumab), but there are no trials in RCC comparing monotherapy with a PD-1 and a CTLA-4 inhibitor.

10. **C.** See individual drug sections under section “Treatment” of the chapter. Everolimus is an mTOR inhibitor, sorafenib is a multitargeted TKI, lenvatinib is correctly matched (multitargeted TKI), and sunitinib is also a multitargeted TKI.

11. **B.** See section “Treatment.” These three treatment-induced adverse drug reactions are common with all of the FDA-approved VEGF-pathway inhibitor TKIs used in the treatment of metastatic RCC.

12. **C.** See section “Treatment” and Table e161-4 and Fig. e161-4. First-line favorable risk metastatic RCC patients should be treated with a regimen combining an VEGF TKI with immunotherapy, such as lenvatinib plus pembrolizumab. Single-agent interferon alpha is no longer recommended in the NCCN guidelines, as novel immunotherapy options have improved clinical efficacy. Temsirolimus and ipilimumab + nivolumab are recommended in patients with intermediate/poor risk disease.

13. **B.** See section “Treatment” and Table e161-4 and Fig. e161-4. Ipilimumab plus nivolumab is the only regimen among the available choices to have a category 1 recommendation for the treatment of patients with poor-risk metastatic RCC.

14. **A**. See section “Treatment” and Table e161-4 and Fig. e161-4. Cabozantinib has a category 1 recommendation for poor-risk disease based on data from the CABOSUN trial. Single agent nivolumab has a category 1 recommendation, however, would not be considered an option since it is used in the first-line setting. The other options are not appropriate for patients with poor-risk metastatic RCC or have lower levels of evidence: sorafenib and high-dose interleukin-2 have a category 2B recommendation.

15. **B.** See section “Treatment.” This was the only selection among the available options with adverse drug reactions that could be attributed to both lenvatinib and pembrolizumab. Diarrhea, hypothyroidism, and transaminitis can be attributed to both medications. All other choices include one or more adverse drug reactions that are specific to either lenvatinib or pembrolizumab.

Chapter e163: Hematopoietic Cell Transplantation

Dimaggio Elizabeth; Perkins Janelle

KEY CONCEPTS

KEY CONCEPTS

① Hematopoietic cell transplantation (HCT) is a procedure that involves intravenous infusion of hematopoietic stem cells from a donor into a recipient, after the administration of chemotherapy with or without radiation. The rationale is to increase tumor cell kill by increasing the dose of myelotoxic therapies and giving donor hematopoietic stem cells to "rescue" the recipient from the hematologic toxicity. Immune-mediated effects also contribute to the tumor cell kill observed after allogeneic HCT.

② Hematopoietic stem cells used for transplantation can come from the recipient (autologous) or from a related or unrelated donor (allogeneic). If the related donor is a twin, the transplant is referred to as a syngeneic transplant.

③ Human leukocyte antigen (HLA) mismatching of allogeneic donor-recipient pairs at either class I or class II loci increases the risk of graft failure, graft-versus-host disease (GVHD), and worsens survival in the absence of effective GVHD prophylaxis. The ideal donor is one that is matched at HLA-A, B, C, and DRB1.

④ Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood. These stem cells express the CD34 antigen, and the number of $CD34^+$ cells is a clinically useful measure of the number of hematopoietic stem cells. Infusion of a minimum number of $CD34^+$ cells is necessary to ensure posttransplant engraftment. Due to the rarity of these cells in the peripheral blood, mobilization strategies are used to increase the number of $CD34^+$ cells prior to collection procedures.

⑤ Because of clinical and economic advantages, peripheral blood has replaced bone marrow as the most common source of hematopoietic stem cells in the autologous and adult allogeneic HCT setting.

⑥ The purpose of the preparative (or conditioning) regimen in traditional myeloablative transplants is twofold: (a) maximal tumor cell kill and (b) immunosuppression of the recipient to reduce the risk of graft rejection (allogeneic HCT only).

⑦ Reduced-intensity conditioning regimens (including those that are nonmyeloablative) have been developed to reduce early posttransplant morbidity and mortality while maximizing the graft-versus-malignancy (GVM) effect. The advantage of this approach is that patients who would otherwise not be eligible for allogeneic HCT can be offered a potentially curative therapy.

⑧ Transplant-related mortality associated with allogeneic HCT depends on recipient age, recipient performance status, donor source and degree of HLA matching, and disease status. Major causes of death include relapse, infection, organ toxicity, and GVHD. The most common cause of death after autologous HCT is disease relapse; transplant-related mortality is lower than after allogeneic HCT and depends on the conditioning regimen, age, underlying comorbidities, and disease status.

⑨ Patients undergoing allogeneic HCT receive immunosuppressive therapy to prevent GVHD, which inhibits T-cell activation, proliferation, or both. Commonly used GVHD prophylaxis regimens include combinations of tacrolimus, methotrexate, sirolimus, mycophenolate mofetil, or posttransplant cyclophosphamide.

⑩ Initial treatment of acute and chronic GVHD consists of prednisone, either alone or combined with other immunosuppressants. New agents are available for the treatment of steroid-refractory GVHD.

BEYOND THE BOOK

BEYOND THE BOOK

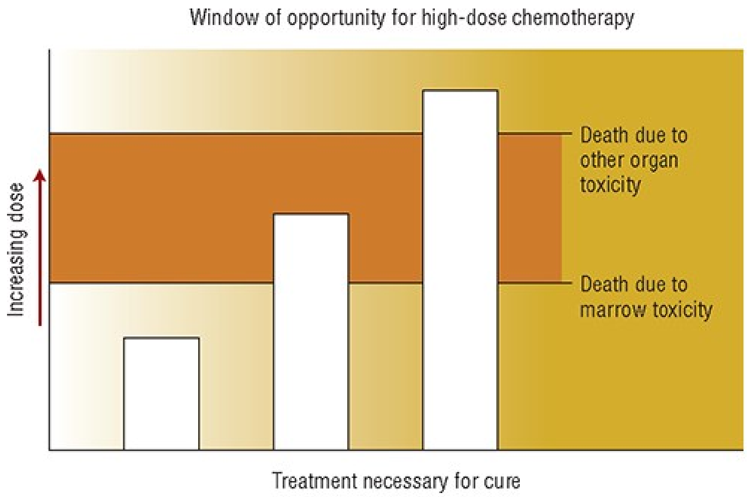
Watch the "What is GVHD?" video available on YouTube and visit the "Hematopoietic Cell Transplantation (HCT)—Clinicians Resource" (select posttransplant care, then chronic GVHD) on bethematchclinical.org. The video gives a brief overview of GVHD for the purposes of patient education. The website provides more detail about the clinical manifestations of chronic GVHD. Both will help students to learn the basics about GVHD in preparation for a more in-depth discussion provided by the chapter.

INTRODUCTION

① Hematopoietic cell transplantation (HCT) is a procedure that involves intravenous infusion of hematopoietic stem cells from a compatible donor into a recipient, usually after the administration of high-dose chemotherapy with or without radiation (called the conditioning or preparative regimen). The original rationale for HCT in the treatment of malignant disease is based on studies showing that many anticancer drugs and radiation have a steep dose–response relationship and that myelosuppression limits the chemotherapy dosage that can be safely administered. Although standard-dose chemotherapy can prolong survival in many cancer patients, most patients are not cured of their disease with this strategy alone. Infusion of hematopoietic stem cells allows the administration of high doses of chemotherapy (as much as 10-fold higher) by reestablishing hematopoiesis. If tumor cells that are resistant to standard doses are sensitive to higher doses of chemotherapy, then tumor cell kill will be greatly increased, and the likelihood of cure would be higher with HCT compared with standard-dose chemotherapy. However, the chemotherapy dose cannot be escalated indefinitely due to the risk of death caused by nonhematologic toxicity (see Fig. e163-1).

FIGURE e163-1

Patients represented by the middle bar are the best candidates for hematopoietic cell transplantation because the technique allows for administration of chemotherapy or radiation in doses that otherwise would be intolerable because of severe myelosuppression.



Window of opportunity for high-dose chemotherapy
Increasing dose
Death due to other organ toxicity
Death due to marrow toxicity
Treatment necessary for cure

HCT is an important modality to treat a variety of malignant and nonmalignant diseases. In the United States, the estimated annual number of allogeneic HCTs exceeds 8,000 while the annual number of autologous HCTs has steadily increased since 2000 with over 12,000 HCTs performed in 2019.[1] The total number of HCTs per year has grown steadily over the past decade because of an increase in the number of patients receiving alternative donor transplants and an increase in the number of patients older than 60 years undergoing transplantation.[1]

The most common malignancies treated with HCT are multiple myeloma, lymphomas, and leukemias and other blood disorders such as myelodysplasia and myeloproliferative syndromes. Many nonmalignant hematologic disorders, including aplastic anemia, thalassemia, and sickle cell anemia; immunodeficiency disorders; and other genetic disorders are also potentially curable with allogeneic HCT. Autologous HCT can also be used to treat select patents with autoimmune diseases, such as rheumatoid arthritis, multiple sclerosis, and systemic lupus erythematous. The role and indications for HCT are discussed in detail within individual disease chapters of this text.

This chapter summarizes the procedures involved in HCT and the common complications associated with HCT. More detailed information on HCT can be found in published reviews and books.[2–4] Information on HCT also can be found on several websites, including http://www.cibmtr.org (Center for International Blood and Marrow Transplant Research [CIBMTR]) and https://bethematch.org/ (National Marrow Donor Program [NMDP]).

HISTOCOMPATIBILITY TESTING AND DONOR SELECTION

② Different types of donors are used in HCT. The choice of donor depends on the diagnosis and disease status of the recipient as well as their age, concurrent comorbidities, and performance status. In *autologous* transplants, patients receive their own hematopoietic stem cells, which were collected and stored before administration of the transplant conditioning regimen. In *syngeneic* transplants, an identical twin serves as the donor. In *allogeneic* transplants, the donor is genetically not identical to the recipient but shares some common cell surface antigens called human leukocyte antigens (HLAs). These antigens are encoded by the major histocompatibility complex (MHC), a cluster of genes located on the sixth chromosome.[5] The MHC contains three distinct regions designated as class I, class II, and class III. Class I and class II genes encode for HLA; products of class III genes have other important roles in the immune system. Class I and class II HLA antigens differ in their tissue distribution, structure, and function. Their primary function is to aid the immune system in recognizing cells or tissues as "self" or "nonself." The genes (and the corresponding antigens they encode for) important in HCT are the class I antigens, HLA-A, HLA-B, and HLA-C and the class II antigen, HLA-DRB1.[5] Class II antigens also include HLA-DQ and –DP. Because of the polymorphism of the HLA system, there are many different HLA antigens within each different class of HLA. To reduce the chance of graft rejection and graft-versus-host disease (GVHD), a donor is chosen based on how many of these HLA antigens are the same as those of the recipient.[5] Thus, an ideally matched donor would be an "8/8" match, matching at HLA-A, -B, -C, and –DRB1.

To identify a suitable allogeneic donor, both the recipient and potential donors are HLA typed (ie, specific HLA antigens are identified); the potential donor who is most closely matched is generally chosen to be the transplant donor. HLA typing is accomplished by DNA-based techniques that use polymerase chain reaction (PCR) amplification of specific HLA genes from genomic DNA. DNA typing methods are categorized by the level of discrimination they provide in defining the sequence of an HLA gene.[5] Low-resolution methods provide limited sequence information about a particular HLA gene and are typically used to identify sibling donors. However, low-resolution techniques cannot distinguish the extremely polymorphic nature of many of the HLA antigens. HLA antigens are characterized by thousands of genetic variations (alleles), and each allele may correspond to a unique HLA molecule. High-resolution typing techniques (eg, sequence-specific priming or next-generation sequencing) can characterize different alleles and are used to identify suitable unrelated donors.

③ The degree of HLA mismatching correlates with the risk of graft rejection, GVHD, and survival.[5] Mismatches at HLA-A, HLA-B, HLA-C, and HLA-DRB1 are similarly associated with increased risk of GVHD and mortality.[5] HLA-DQB1 and –DPB1 mismatching are less predictive of negative outcomes, which suggests an 8/8 match is as beneficial as a 10/10 or 12/12 match. As the number of mismatches increases, the risk of GVHD and transplant-related mortality also increases. In the search for an allogeneic donor, the patient's siblings are typed first. About 30% of Americans have an HLA-identical sibling. In an effort to offer allogeneic HCT to patients who lack an HLA-identical sibling donor, alternative donors are being used. The most common type of alternative donor is an individual unrelated to the recipient who is fully HLA matched. With improved HLA typing techniques and better supportive care, most reported outcomes with matched unrelated donors are not significantly different than those reported with related sibling donors.[6] To facilitate the identification of unrelated donors, the NMDP (https://bethematch.org) was started in 1986. To date, the NMDP has access to more than 39 million donors worldwide through agreements with international cooperative registries and has facilitated more than 105,000 unrelated donor transplants. Although it is the transplant center's responsibility to select the donor, the NMDP recommends that selected donor and recipient be matched at HLA-A, B, C, and DRB1 by high-resolution typing when possible for bone marrow or peripheral blood HCT.[7,8] If more than one suitable HLA-matched unrelated donor is identified, other factors can be used to select the donor, such as younger age, being male or a nulliparous female, and negative cytomegalovirus (CMV) serostatus.

The likelihood of a patient finding an HLA-matched unrelated donor through NMDP ranges from 29 to 79% depending on the prevalence of the recipient's HLA type, race, and ethnic background.[7] With the current size and racial make-up of the NMDP registry, the matching likelihood is higher for White patients than for patients from other racial or ethnic groups. Agreements between NMDP and international registries may improve the likelihood of finding donors for non-White patients, and NMDP actively promotes participation among non-White donor volunteers. Another potential limitation in finding an unrelated donor is the time needed to search for a potential donor candidate. Patients with relatively common HLA genotypes have shorter search times than those with less common genotypes. Some donor searches may take several weeks and patients with acute leukemia can relapse while waiting for completion of the search. If an initial search yields few or no donors, transplant centers will usually begin to investigate alternative donor options.

Alternative donor options include mismatched unrelated donors, related haploidentical donors, or umbilical cord blood (discussed in the next section).[7] Potentially useful HLA-mismatched unrelated donors are those who are mismatched at one or, at most, two HLA loci. If minimal mismatching is allowed, the chance of finding an unrelated donor increases significantly. Although mismatched unrelated donor transplants are inferior with respect to GVHD, transplant-related mortality, and overall survival when compared to matched unrelated donors, these transplants do offer a curative therapeutic option in select patients.[7] Research is focused on evaluating the relative effect of mismatches at specific loci to determine if some are less detrimental (permissive) than others in order to improve outcomes. In addition, NMDP recommends testing the recipient for donor-specific HLA antibodies as graft failure is more common when the antibodies are present.[7,8]

Related haploidentical donors are relatives of the recipient with two or more antigen mismatches. Donors can be parents, children, or siblings who have one identical HLA haplotype and one nonidentical haplotype to the recipient. Historically, haploidentical allogeneic transplants (haplo-HCT) resulted in poor outcomes because of high rates of graft failure and GVHD. Strategies to reduce the incidence of graft failure and GVHD have included various methods of T-cell depletion including administration of anti-thymocyte globulin (ATG), alemtuzumab, or posttransplant cyclophosphamide (PTCy).[9,10] Several observational studies have compared outcomes after haplo-HCT to those seen after traditional matched related and unrelated donor transplants and have shown that GVHD and survival outcomes were similar.[11–13] Two parallel prospective studies with identical objectives, eligibility criteria, and clinical endpoints were conducted with reduced-intensity conditioning regimens in either haplo-HCT with PTCy or umbilical cord blood transplant (UCBT).[14] While the trials were not designed for results to be compared directly, patients receiving haplo-HCT had higher rates of engraftment, lower risk of acute and chronic GVHD and less nonrelapse mortality than reported in the UCBT trial. However, relapse rates were lower after UCBT leading to similar progression-free and overall survival between the two studies. These trials reproduce single-center results with haplo-HCT or UCBT and suggest that survival rates with these alternative donor sources are comparable to those observed after matched unrelated donors. Based on these results, a phase III study comparing haplo-HCT or UCBT showed no significant difference in progression-free survival at 2 years. However, overall survival, a secondary endpoint, was lower in patients receiving UBCT compared to those receiving haplo-HCT.[15] While this study suggests an advantage of haplo-HCT over UCBT, choosing an alternative donor in the absence of an HLA-matched sibling or unrelated donor depends on patient characteristics, physician preference, and center experience.

HEMATOPOIETIC STEM CELLS

Hematopoietic stem cells serve as “mother” cells for all blood cells, including erythrocytes, leukocytes, and platelets (see Chapter e106). Stem cells have varying degrees of “stemness.” True pluripotent stem cells can replicate indefinitely and can give rise to stem and progenitor cells of all tissues. Multipotent stem cells, such as hematopoietic stem cells, have the capacity for self-renewal and can differentiate into more than one cell type in a particular tissue lineage. Because of their capacity for self-renewal, hematopoietic stem cells can repopulate the recipient’s marrow, which has been “emptied” by the administration of high-dose chemotherapy, either alone or combined with radiation.

④ Hematopoietic stem cells are rare cells, comprising less than 0.01% of all bone marrow cells. Isolation and quantitative measurement of hematopoietic stem cells are extremely difficult because of their rarity and their similar appearance to other cells. For these reasons, surrogate markers are used to measure the number of stem cells. CD34 is an antigen expressed on hematopoietic stem cells and other early progenitor cells. The number of cells expressing the CD34 antigen ($CD34^+$ cells) can be determined by flow cytometry and has become the standard method of measuring hematopoietic stem cell content.

Hematopoietic stem cells are found in the bone marrow, peripheral blood, and umbilical cord blood (UCB). Hematopoietic stem cells from the bone marrow are obtained by multiple aspirations from the anterior and posterior iliac crests while the donor is under general anesthesia. The procedure takes about 1 hour and yields 200 to 1,500 mL, depending on the size of the donor. In allogeneic bone marrow transplantation (BMT), the marrow stem cells are given to the recipient 12 to 24 hours after harvest. In autologous BMT, the marrow is frozen and stored until needed. After intravenous infusion, the marrow stem cells enter the systemic circulation and find their way to the bone marrow cavity, where they reseed and grow in the bone marrow microenvironment. Although the donor experiences local soreness for a few days, the procedure usually is well tolerated, with no delayed complications resulting from the marrow aspiration. The major risk of serving as a marrow donor is the risk of undergoing general anesthesia.

Hematopoietic stem cells in peripheral blood (peripheral blood stem cells [PBSCs]) are found in the mononuclear fraction of white blood cells (lymphocytes and monocytes) and are collected by a procedure called leukapheresis (or apheresis). This is an outpatient procedure that involves withdrawal of blood from a vein (through a specialized IV catheter), selective removal of mononuclear cells (containing the hematopoietic stem cells) by an apheresis machine, and reinfusion of the unneeded blood components back to the patient. During this process, about 10 to 15 L of blood is processed over several hours during each daily apheresis session. Most of the blood cells are returned to the donor, and each apheresis yields about 200 mL of cells. Leukapheresis is continued daily until a target number of $CD34^+$ cells (which include hematopoietic stem cells) are collected or until the collections are discontinued due to poor $CD34^+$ cell yield.

The number of hematopoietic stem cells that circulate in peripheral blood normally is too low for apheresis to be technically feasible. Without mobilization techniques, at least six apheresis are usually required to collect a sufficient number of PBSCs. Several methods have been used clinically to “mobilize” hematopoietic stem cells from the bone marrow into peripheral blood for use in HCT. Figure e163-2 shows representative schemas for mobilization and collection of PBSCs. The most commonly used mobilization method in both donor populations (healthy allogeneic donors and autologous donors) is the administration of the recombinant hematopoietic growth factor, granulocyte colony-stimulating factor (G-CSF [filgrastim]), usually at a dose of 10 μg/kg/day.[16–18] Chemotherapy followed by G-CSF in patients undergoing autologous HCT increases the number of PBSCs to a greater extent than growth factor alone. This approach is more expensive than single-agent G-CSF and is associated with more adverse drug reactions, but the number of apheresis is generally reduced, and the additional chemotherapy may further reduce tumor burden before transplant. However, these benefits have not translated into improved transplant outcomes, so this approach is generally not used.[16,17] Pegfilgrastim (pegylated filgrastim) has also been evaluated in the mobilization setting, either alone or after chemotherapy (6 and 12 mg doses). Its prolonged half-life of 33 hours allows for single-dose administration, increasing patient convenience. Studies of single agent pegfilgrastim are limited by small numbers and report varying degrees of success.[16,17] The combination of pegfilgrastim and chemotherapy mobilization results in similar $CD34^+$ cell collections and transplant-related outcomes to chemotherapy and G-CSF mobilization.[16,17]

The first G-CSF biosimilar was introduced in Europe in 2008. Professional organizations were initially reluctant to recommend these agents for stem cell mobilization due to a paucity of safety and efficacy data. However, several prospective trials comparing biosimilar products to the reference product have been published. A meta-analysis summarized the results in over 1,800 subjects which included healthy donors and patients with hematologic malignancies who used biosimilar agents to collect PBSCs. Mobilization with biosimilars resulted in expected $CD34^+$ stem cell yields with similar posttransplant engraftment and adverse effects to G-CSF, which suggests that biosimilars are an acceptable option in mobilization, especially given their potential cost-savings.[18,19]

Plerixafor is a novel inhibitor of the CXCR4 chemokine receptor that is FDA approved as a mobilizing agent in combination with G-CSF in autologous transplant candidates. When plerixafor is combined with G-CSF, higher $CD34^+$ cell yields, fewer apheresis sessions, increased likelihood of achieving $CD34^+$ target yields, and lower graft failure rates are observed compared to single-agent G-CSF.[16,17] Due to these advantages, the combination of plerixafor and G-CSF is routinely used to mobilize stem cells in autologous HCT patients.[18] However, because many patients can mobilize efficiently with G-CSF alone and plerixafor is expensive, transplant centers generally use a risk-adapted or preemptive approach to identify which patients are appropriate candidates for plerixafor. One approach is to give plerixafor to patients with certain characteristics that have been associated with a high risk of poor mobilization (ie, risk-adapted approach). These characteristics include older age, diagnosis of non-Hodgkin lymphoma (NHL), extensive chemotherapy history, previous radiation therapy, previous exposure to lenalidomide or purine analogs, previous mobilization failure, and low pre-apheresis circulating peripheral blood $CD34^+$ ($PBCD34^+$) cell counts.[20] However, these patient characteristics are not accurate predictors of poor mobilization outcomes and thus patients may be either over or under treated. Another approach is a preemptive strategy, which identifies poor mobilizers based on $PBCD34^+$ cell counts on day 4 or 5 of the G-CSF administration or on the first apheresis collection. Low numbers of $CD34^+$ cells after the G-CSF administration have been associated with mobilization failure. Patients who do not have a minimal number of $CD34^+$ cells receive plerixafor.[16–18] Many transplant centers use these preemptive approaches to guide their mobilization strategies, thereby limiting plerixafor use to patients who are not likely to obtain the target $CD34^+$ yield. These algorithms have been reported to improve initial mobilization rates while efficiently managing resources.[20]

In about 20% to 30% of autologous transplant candidates, an optimal number of $CD34^+$ cells will not be obtained after the first attempt with G-CSF mobilization.[20] Several strategies for overcoming the obstacle of poor mobilization have been evaluated, including remobilization with the same or higher doses of the G-CSF, previously used mobilization regimen or a combination of chemotherapy and a hematopoietic growth factor, if chemotherapy is indicated.[20] Each of these remobilization strategies has been used with varying success. Unfortunately, these strategies are associated with failure rates that exceed 70%. Bone marrow harvest may be an option if other strategies fail.

Current guidelines recommend that plerixafor be used in remobilization regimens for patients failing primary mobilization attempts, regardless of whether it was used in the primary mobilization.[16–18] The use of plerixafor combined with chemotherapy and G-CSF may be a promising strategy, but further data are needed to better understand the appropriate use of this regimen. The selection of a secondary mobilization regimen should be based on patient-specific factors and clinician judgment.

The number of $CD34^+$ cells infused correlates significantly with the rate of neutrophil and platelet recovery after high-dose chemotherapy.[16,17] Rapid neutrophil recovery usually is observed in patients who receive at least 2×10^6 $CD34^+$ cells/kg (body weight of recipient). More rapid platelet recovery is observed when at least 5×10^6 $CD34^+$ cells/kg are transplanted compared with lower cell doses. As a result, current guidelines recommend 2×10^6 $CD34^+$ cells/kg as a minimum number to collect for autologous transplant, with an optimal target of 5×10^6 $CD34^+$ cells/kg.[18] The decision to use a collection yield of less than 2×10^6 $CD34^+$ cells/kg should be limited to those cases in which the potential benefit of a HCT outweighs the risks of infusing a suboptimal $CD34^+$ cell dose. If a second transplant (ie, tandem transplant) is planned, a minimum of 4×10^6 $CD34^+$ cells/kg may be collected and divided into two equal aliquots, one for each transplant.

⑤ The use of peripheral blood instead of bone marrow as a source of hematopoietic stem cells offers several clinical and economic advantages. For autologous transplant patients, the most clinically important advantage is that patients who receive mobilized PBSCs experience more rapid hematopoietic engraftment. Although engraftment of all lineages is more rapid when PBSCs are used, the most significant effect is observed with platelet recovery. Patients who receive mobilized PBSCs experience platelet recovery as much as 2 to 3 weeks earlier and require fewer platelet transfusions than those who receive bone marrow stem cells. As a result, patients usually are discharged earlier from the hospital, so the overall cost of autologous HCT is reduced with the use of PBSCs. PBSCs may be less likely to be contaminated with malignant cells compared with marrow stem cells. Finally, because PBSCs are collected from the mononuclear cell fraction, a fraction that also contains immunocompetent cells (eg, natural killer [NK] cells and T lymphocytes), some investigators believe that infusion of PBSCs represents a form of "adoptive immunotherapy." In this model, NK cells and lymphocytes targeted against tumor cells help to kill residual tumor cells. As a result of these clinical and economic advantages, peripheral blood has replaced bone marrow as the source of stem cells in the autologous setting.

Peripheral blood has also become the predominant source of hematopoietic stem cells in adults undergoing allogeneic HCT.[1] About two-thirds of allogeneic HCTs performed in adults currently come from PBSCs harvested from normal donors receiving G-CSF mobilization. G-CSF is generally well tolerated in the normal donor population. Short-term adverse drug reactions are similar to those seen in cancer patients receiving G-CSF (eg, bone pain, headache, fever, arthralgias, malaise). Although there are concerns about increased risk of acute myeloid leukemia (AML) in healthy subjects given G-CSF, no higher risk has been observed.[21]

Randomized controlled trials and meta-analyses have shown that the stem cell source can influence posttransplant outcomes in allogeneic HCT. Traditionally, matched-related PBSC transplants have been associated with a more rapid hematopoietic recovery and required fewer transfusions compared with patients receiving bone marrow.[22] The difference in the rate of engraftment may be related to the threefold higher numbers of CD34$^+$ cells infused in recipients of PBSC transplants. Although an increased risk of acute GVHD or transplant-related mortality in patients receiving allogeneic PBSC transplants has not been reported, a higher risk of chronic GVHD has been observed in many retrospective studies and meta-analyses.[22] The Blood and Marrow Transplant Clinical Trials Network (BMT CTN) reported results from a trial that randomized 551 patients to allogeneic PBSC or bone marrow from matched unrelated donors.[23] Two years after transplant, no differences in overall survival, relapse, acute GVHD, or non-relapse mortality were observed. However, a higher incidence of chronic GVHD was reported in patients who received PBSC transplants. Most studies of the effect of stem cell source on transplant-related outcomes have focused on transplants following myeloablative conditioning. In a retrospective study of patients with hematologic malignancies who received reduced intensity unrelated donor transplants with either PBSCs or bone marrow, the CIBMTR reported that time-to-engraftment, risks of acute or chronic GVHD, relapse, nonrelapse mortality, and overall survival were not significantly different between the two groups. Subgroup analysis suggests that GVHD prophylaxis may impact survival in this patient population and warrants further evaluation.[24] The selection of the optimal source of hematopoietic stem cells for an individual patient should be based on the risk of relapse, chronic GVHD, graft failure, and donor preference.

Hematopoietic stem cells found in UCB are an attractive source for several reasons.[25] Because the stem cells are collected from placental blood, there is a low risk of transmissible infectious diseases, no risk to the mother or the baby, and the cells are immediately available. UCB initially was obtained from siblings, but now recipients of transplants from unrelated donors account for almost all patients who receive UCB transplants. More than 800,000 UCB units are available in more than 100 UCB banks, and more than 40,000 unrelated UCB transplants have been performed worldwide. However, cord blood use as a stem cell source is decreasing.[1] This decline in cord blood source is related to the increasing use of haplo-HCT and has been attributed to increasing costs, posttransplant infections, and the need for multiple cord blood units to increase stem cell dose.[25]

A major limitation of UCBT is the small volume of blood collected, usually 60 to 150 mL with resultant low numbers of CD34$^+$ cells. This has led to “pooling” two or more units of UCB for one recipient (referred to as double cord transplant). Despite increasing CD34$^+$ cell doses through use of double cord products, the time to engraftment following UCBT is longer compared to other cell sources. Additional interventions such as ex-vivo expansion of UCB stem cells prior to transplant have reported encouraging results but ongoing testing is needed to confirm long-term safety and efficacy.[25]

APPROACHES TO ERADICATE MALIGNANT CELLS

Conditioning Regimens

⑥ The purpose of the pretransplant conditioning regimen (also called the preparative regimen) depends on the type of transplant and the indication for its use. In the autologous setting, conditioning is used to eradicate malignant cells.[26] This is also the case in allogeneic HCT for malignant diseases, but the conditioning regimen also serves a dual purpose to suppress the recipient’s immune system to allow for donor cell engraftment. Conditioning regimens can be myeloablative, reduced intensity, or nonmyeloablative.[27] Myeloablative conditioning (MAC) regimens contain high doses of chemotherapy with or without radiation that would lead to life-threatening or fatal myelosuppression if hematopoietic stem cells were not infused. Patients undergoing autologous HCT receive only MAC regimens. Patients undergoing allogeneic HCT can receive MAC, reduced-intensity (RIC), or nonmyeloablative (NMA) conditioning regimens. RIC and NMA regimens consist of lower doses or different types of chemotherapy or lower doses of radiation than MAC regimens, resulting in less toxicity. Both were developed after the observation was made that some of the antitumor effect of the allogeneic transplant was mediated by a reaction between the donor’s transplanted immune system and the recipient’s cancer cells. This meant that high doses of chemotherapy, radiation, or both may not be needed in all patients. Because RIC or NMA conditioning regimens use lower doses of chemotherapy or radiation or less toxic drugs, older patients and those with comorbidities can be offered potentially curative allogeneic transplants. Table e163-1 lists chemotherapeutic agents frequently used in conditioning regimens, the doses used, and their dose-limiting toxicity in the transplant setting. Also listed are common regimens that include the agents listed.

TABLE e163-1

Dose-Limiting Nonhematologic Toxicities for Selected Chemotherapeutic Agents Included in Myeloablative Conditioning Regimens in Hematopoietic Cell Transplantation and Examples of Commonly Used Conditioning Regimens

Drug	Conventional Dose (mg)	HCT Dose (mg/m^2)	Dose-Limiting Toxicity	Commonly Used Regimens[a]
Busulfan (IV)	2 (PO)	300-780	Hepatic	BuCy, BuFlu
Carboplatin	400	2,000	Hepatic, renal	Carboplatin + E + Cy or Mel
Carmustine (BCNU)	200	1,200	Pulmonary, hepatic	BEAM, BEAC, CBV
Cyclophosphamide	1,000	7,500	Cardiomyopathy	CyTBI, FluCy + TBI
Etoposide	300-600	2,400	Mucositis	EtopTBI, BEAM, BEAC,
Melphalan (IV)	28-42 (PO)	140-200	Mucositis	Single agent melphalan, BEAM, FluMel ± TBI
Thiotepa	20-50	750	Mucositis, central nervous system	BCNU + Thiotepa
				Thiotepa + Bu + Cy
Fludarabine	125	125-240	Neurotoxicity	FluMel ± TBI, BuFlu, FluTBI

[a] Doses for regimens are given in the body of the text

BCNU, carmustine; BEAC, BCNU, etoposide, cytarabine, cyclophosphamide; BEAM, BCNU, etoposide, cytarabine, melphalan; Bu, busulfan; CBV, cyclophosphamide, BCNU, etoposide; Cy, cyclophosphamide; E or V, etoposide or VP-16; Flu, fludarabine; Mel, melphalan; TBI, total body irradiation.

Myeloablative Conditioning Regimens

MAC regimens usually include at least one anticancer drug with a relatively steep dose-response curve and myelosuppression as their dose-limiting toxicity, such as an alkylating agent. Cyclophosphamide, melphalan, busulfan, and carmustine are examples of chemotherapy agents commonly used in MAC regimens. They are combined with other agents that have additive or synergistic effects in specific types of cancers, or additional alkylating agents may be used.

Total-body irradiation (TBI) is also used in some pretransplant conditioning regimens. In patients with malignant disease, the rationale of TBI is to eradicate malignant cells located in areas inaccessible to the systemic circulation and thus to the chemotherapeutic agents (eg, central nervous system and testicles). TBI also has significant immunosuppressive activity that prevents rejection of the donor cells (ie, graft rejection) and facilitates successful engraftment.[28] Historically, TBI doses in MAC regimens ranged from 10 to 16 Gy (1,000-1,600 rads or cGy), which is more than twice the lethal myelosuppressive dose of radiation for a normal person. TBI given at high doses is typically fractionated (split over 3-4 days, once or twice a day) rather than given as a single dose. Fractionated TBI has an improved therapeutic ratio compared with single-dose administration, that is, the destruction of more leukemic cells and marrow stem cells while sparing other normal tissues such as lungs, liver, eyes, and cartilage. The acute toxicities of TBI consist of fever, nausea, vomiting, diarrhea, dysphagia, anorexia, xerostomia, mucositis, erythema, rash, alopecia, fatigue, myelosuppression, and tender swelling of the parotid gland. Pneumonitis and sinusoidal obstruction syndrome can occur, but rates have declined with improved TBI delivery and supportive care measures. Long-term complications of TBI-containing regimens include cognitive deficiencies, pituitary dysfunction, cardiac dysfunction, hypothyroidism, cataract formation, growth retardation, osteopenia, carcinogenesis, permanent reproductive sterility, and secondary malignancies.[28]

Based on its immunomodulatory and antineoplastic effects, cyclophosphamide (60 mg/kg/day for 2 days) is commonly combined with TBI (CyTBI). Other chemotherapy agents have been used with TBI, including fludarabine and etoposide, but there is no evidence to suggest that any of these combinations are more effective than CyTBI. Due to the toxicities seen with high-dose TBI, chemotherapy-only regimens also have been developed and may be preferred depending on patient characteristics such as diagnosis, stage of disease, performance status, or age. For example, in patients with acute myeloid leukemia (AML), TBI conditioning regimens do not confer a survival advantage.[29] In contrast, patients with acute lymphoid leukemia (ALL) who received TBI-containing regimens had similar survival with improved relapse outcomes.[30] Many non-TBI regimens contain busulfan due to its activity against a variety of malignancies. Busulfan can either be given IV or orally, although IV administration is more common due to more consistent systemic exposure. The use of IV busulfan-containing regimens has been associated with improved survival compared to TBI-containing regimens in patients with myeloid malignancies.[31,32] Systemic exposure of busulfan has been shown to correlate with both efficacy and toxicity. At some transplant centers, plasma busulfan concentrations are monitored, and doses are adjusted to target busulfan exposure with improved patient outcomes.[31,32] However, variability between transplant centers make it difficult to interpret and compare the results. To overcome this barrier, an American Society for Transplantation and Cellular Therapy (ASTCT) committee recommends that busulfan plasma exposure units be standardized across institutions globally and reported as AUC in mg × h/L.[32] Examples of common regimens that use busulfan include busulfan and cyclophosphamide (BuCy) or busulfan and fludarabine (BuFlu).

Conditioning regimens used in autologous HCT are exclusively myeloablative and usually include at least one alkylating agent with other agents added that may have specific activity against the tumor type being treated.[26,33] TBI is not commonly used and is not included in the conditioning regimen in patients who have received prior radiotherapy. MAC regimens commonly used in patients with lymphoma include BEAM (BCNU [carmustine], etoposide, cytarabine, and melphalan), BEAC (BCNU, etoposide, cytarabine, cyclophosphamide) or CBV (cyclophosphamide, BCNU, and etoposide).[33] To reduce BCNU-related toxicities and due to periodic shortages of BCNU, substitute agents such as bendamustine are being evaluated in these lymphoma regimens. Rituximab was previously added in patients with CD20-positive lymphomas, but a recent CIBMTR registry study found no benefit in adding it to BEAM.[34] Single-agent melphalan (140-200 mg/m^2) is the standard conditioning regimen for patients undergoing autologous HCT for myeloma. The addition of other agents to melphalan has not been proven to be superior to melphalan alone.[26]

Reduced-Intensity and Nonmyeloablative Conditioning Regimens

⑦ Donor T cells contribute to the tumor cell kill and prevention of relapse observed after allogeneic HCT, an effect referred to as the graft-versus-malignancy (GVM) effect. The GVM effect may be as important as the anticancer effect of the conditioning regimen. With the recognition of the importance of GVM in allogeneic HCT, the use of less intensive conditioning regimens has become increasingly common. These RIC regimens have shown to be less toxic but with adequate efficacy in many circumstances to increase the availability of HCT to populations previously excluded due to the risk of non-relapse mortality.[27]

RIC regimens contain ≥ 30% lower doses of chemotherapy or radiation, or less toxic agents, and were developed to take advantage of the GVM effect but with a lower risk of regimen-related toxicity than that of MAC regimens.[27] The major advantage of RIC is that potentially curative transplants can be offered to patients who typically would not be considered for allogeneic HCT because of their unacceptably high risk of transplant-related complications due to increased age or moderately compromised organ function. The use of RIC regimens has steadily increased in patients aged 50 years and older.[1] In addition, because of the lower rate of toxicity, allogeneic HCT with RIC can be offered to patients who have relapsed after traditional myeloablative autologous or allogeneic transplants, provided they are healthy enough to tolerate a second transplant. Because RIC regimens may not be completely myeloablative, host hematopoiesis can persist and lead to mixed chimerism (ie, blood cells from both donor and recipient are present) (see Fig. e163-3).[35] Several studies have reported significant correlations between donor T-cell chimerism levels and the risk of graft rejection, GVHD, and relapse. For example, a low percentage of donor T and NK cells present on day 14 has been associated with graft rejection, but high T-cell donor chimerism on day 28 has been associated with acute GVHD. Achievement of full donor chimerism was associated with better GVM effect and longer progression-free survival. These data suggest that monitoring donor chimerism after transplant may allow early interventions to prevent graft rejection or relapse.[35]

FIGURE e163-3

Schema for nonmyeloablative transplantation for hematologic malignancy. Recipients (R) receive a reduced-intensity conditioning regimen and an allogeneic hematopoietic cell transplant (HCT). Initially, mixed chimerism is present with the coexistence of donor (D) cells and recipient-derived normal and leukemia/lymphoma (R_L) cells. Donor-derived T cells mediate a graft-versus-host hematopoietic effect that eradicates residual recipient-derived normal and malignant hematopoietic cells. Donor lymphocyte infusions (DLIs) can be administered to enhance graft-versus-malignancy effects.

Several RIC regimens that vary in their cytotoxic, myelosuppressive, and immunosuppressive activity have been developed.[27] Most regimens include fludarabine (125-240 mg/m^2) because of its potent immunosuppressive activity, combined with either low-dose TBI (at doses up to 8 Gy [800 rad]) or an alkylating agent, such as cyclophosphamide (2-3.6 g/m^2 or 120-200 mg/kg), busulfan (less than 9 mg/kg [or intravenous equivalent]), or melphalan (less than 140 mg/m^2). ATG or alemtuzumab is sometimes given for additional immunosuppression, and other purine analogs (eg, pentostatin or clofarabine) are sometimes used instead of fludarabine. Many of these regimens are myeloablative but are defined as RIC because of the lower doses of chemotherapy and the reduced toxicity associated with these regimens as compared to MAC regimens.[27]

Some RIC regimens are considered nonmyeloablative because they result in little to no myelosuppression and do not require hematopoietic cell support for recovery of hematopoiesis. NMA regimens are associated with little regimen-related toxicity but are similar to other RIC regimens in that they are sufficiently immunosuppressive to allow for full engraftment of donor immune effector cells. Over the last two decades, transplant-related mortality and overall survival outcomes have continued to improve with nonmyeloablative transplants, further supporting their use in older patients with high comorbidity burden.[36] Two of the most common NMA regimens are fludarabine (25 mg/m^2/day for 3-5 days) combined with cyclophosphamide (60 mg/kg/day × 2 days) plus TBI (less than or equal to 2 Gy [200 rad]), or fludarabine plus TBI. Although these regimens are clearly nonmyeloablative, the distinction may be more difficult with other regimens as definitions remain somewhat arbitrary.

Transplant-related outcomes, such as nonrelapse mortality, relapse rate, and overall and progression-free survival, vary depending on the specific regimen, disease type and status (eg, advanced disease, and residual disease) at the time of transplant, donor type, and patient age, performance status, and comorbidities. In general, regimen-related toxicity and nonrelapse mortality are lower than that of historical or concurrent control participants receiving MAC regimens in these nonrandomized comparisons.[27] This is remarkable considering the older age and higher prevalence of comorbidities in patients receiving RIC transplants. Of concern, however, has been an increased rate of relapse in patients receiving RIC regimens in some comparisons, resulting in similar overall survival. This finding depends on the RIC regimen, and patient and disease characteristics. Randomized trials comparing MAC versus RIC regimens to date have included primarily patients with AML or myelodysplastic syndrome (MDS). Results have been mixed with nonrelapse mortality, relapse and overall survival, most likely due to the heterogeneity of patient populations (eg, age, diagnosis, cytogenetic risk) and regimens used.[27] The BMT CTN conducted a large randomized trial comparing RIC versus MAC in patients with high-risk AML or MDS, and long-term follow-up results have been reported.[37] Eligibility criteria included age less than or equal to 65, disease in complete remission and minimal comorbidities. This trial was halted early because a significantly lower relapse rate in the MAC arm of the study was observed. With a longer follow up, patients who received MAC had significantly longer overall survival at 4 years versus the RIC recipients; the survival benefit was primarily observed in AML patients. Patients who received MAC had higher treatment-related mortality, but this was offset by the significantly lower relapse rate.[37] The investigators concluded that the results support the use of MAC for patients who are less than 60 years of age with high-risk AML or MDS.[37]

Posttransplant Therapy

Relapse of primary disease remains the most common cause of death for both allogeneic and autologous HCT patients. As a result, much research has been directed at both preventing and treating posttransplant relapse or progression of disease.[38–40] Posttransplant therapy can be categorized either as “maintenance (or consolidation) therapy” or “salvage therapy.” Maintenance/consolidation therapy is used to prevent relapse whereas salvage therapy is given to treat active relapse. Methods to identify relapsed disease for many hematologic malignancies have become quite sensitive, and disease can often be detected at the molecular level (ie, minimal residual disease) and used to direct posttransplant therapy. Several posttransplant therapies have been evaluated both in the maintenance and salvage settings, including immunotherapy, conventional chemotherapy, and targeted therapy. The ideal posttransplant therapy should be clinically effective, well-tolerated, and should not worsen other recognized posttransplant complications such as cytopenias, infections, or GVHD.[40] Relapse after autologous transplant can often be treated with standard doses of chemotherapy, a second autologous transplant, chimeric antigen receptor (CAR) T-cell therapy, or an allogeneic transplant, depending on the diagnosis, disease status, side effects, response, and duration of response to the first transplant. Treatment options for most patients who relapse after allogeneic HCT are more limited, and the prognosis is generally poor. Disease-specific chemotherapy and immunotherapy can be considered for some patients. A second allogeneic HCT may be considered but is associated with a mortality rate of up to 45%.[39]

Immunotherapy

The rationale for posttransplant immunotherapy after allogeneic HCT is based on the GVM effect. To take advantage of the GVM effect in patients who relapse after allogeneic HCT, immunosuppressive therapy being used for GVHD is withdrawn as quickly as possible without inducing a serious GVHD flare. In rare cases, this is enough to reinduce a remission, but further therapy is usually required. This is not a viable option in patients with active GVHD.

A commonly used form of posttransplant immunotherapy is donor lymphocyte infusion (DLI).[41] Lymphocytes are collected from the same donor who provided hematopoietic stem cells for the original allogeneic transplant, thus limiting this option to patients with available donors. They can be given as therapeutic (given in the relapse setting), preemptive (given if minimal disease is detected following HCT), or prophylactic (given in patients at high-risk for relapse) therapy, although the role of the latter two remains unclear. Response to DLI is disease-specific and is more effective with lower malignancy burden; in lymphoid malignancies, better results are seen in indolent lymphomas compared to aggressive lymphomas, myeloid malignancies have shown intermediate results.[41] More than 80% of patients with CML who are in cytogenetic or molecular relapse respond to DLI. The response rate of patients in more advanced phases is about 15% to 30%. Although the time-to-response is delayed (median, 3-4 months), patients often have a durable molecular remission to DLI. Response rates to DLI of patients with AML and MDS are generally lower (15%-30%) than the rates of patients with CML. Posttransplant DLI has little benefit in patients with relapsed ALL, which may be related to the rapid proliferation of acute leukemia during the often prolonged time-to-response after DLI. Patients with relapsed AML after HCT are more likely to achieve a complete response to DLI if they had a longer remission period after transplant and have some GVHD after the DLI; low tumor burden, remission at the time of DLI, and good-risk cytogenetics have also been shown to be favorable characteristics. Administration of induction chemotherapy or therapeutic agents such as 5-azacitidine before DLI administration may improve the antitumor activity of DLI in patients with AML or other rapidly proliferating malignancies.[41]

The most serious complications of DLI are pancytopenia and GVHD, and DLI is not usually given to patients with active GVHD. The cytopenias generally are transient and can be treated with hematopoietic growth factors. Some patients may have a more prolonged course of aplasia with the associated risk of infection, bleeding, and anemia, and these patients may benefit from another infusion of donor hematopoietic stem cells.

Chimeric antigen receptor (CAR) T-cell therapy is another option in patients with lymphoid malignancies, such as non-Hodgkin lymphoma, B-cell lineage ALL, or multiple myeloma, who relapse after HCT. The use of these therapies is discussed in the respective disease-specific chapters.

Monoclonal Antibodies

Although rituximab is a mainstay in the treatment of non-Hodgkin lymphomas, its use as maintenance therapy in the posttransplant setting for these patients has not been associated with a consistent benefit. Routine use of rituximab maintenance is not recommended in diffuse large B-cell lymphoma, but it is recommended for high-risk follicular lymphoma and mantle cell lymphoma.[38] Rituximab may be useful in combination with other active agents for salvage therapy of posttransplant relapse.

Brentuximab vedotin (anti-CD30 antibody conjugated to monomethyl auristatin E, a microtubule-disrupting agent) was evaluated as maintenance therapy in a randomized placebo-controlled study in patients with Hodgkin lymphoma after autologous HCT.[38,42] Progression-free survival at 5 years was significantly improved in patients randomized to brentuximab. Consistent benefit was seen across all subgroups that were analyzed, but the benefit of brentuximab was more pronounced in patients at higher risk for relapse. The most frequent adverse drug reactions in the brentuximab group were peripheral sensory neuropathy and neutropenia. These results led to the FDA approval of brentuximab administration after autologous HCT and has been increasingly adopted into clinical practice. Other monoclonal antibody agents being evaluated for use as maintenance therapy after HCT in Hodgkin lymphoma are the anti-programmed cell death-1 (anti-PD-1) checkpoint inhibitors, pembrolizumab, and nivolumab.[38]

Chemotherapy or Targeted Therapy

Tyrosine kinase inhibitors (TKIs), such as imatinib, dasatinib, and nilotinib, are used to prevent and treat relapse after allogeneic HCT in patients with CML and Philadelphia chromosome–positive (Ph+) ALL.[38,43] In patients with CML who experience hematologic relapse (presence of leukemic blasts in blood or bone marrow) after allogeneic HCT, imatinib can induce complete hematologic responses (disappearance of leukemic blasts) and complete cytogenetic responses (disappearance of cytogenetic markers of disease) in most patients. Similar outcomes in patients with Ph+ ALL have been reported. TKIs may be given soon after transplant to prevent relapse.[38,43] Patients with Ph+ ALL and CML without evidence of disease after transplant who are treated with TKIs to prevent relapse appear to have sustained cytogenetic remissions (without evidence of cytogenetic markers of disease). TKIs are generally well tolerated after transplant. Commonly reported adverse drug reactions include neutropenia, thrombocytopenia, liver function abnormalities, edema, and muscle pain, which may require dosage reductions or discontinuation. Large comparative studies will be required to define the benefit of TKIs after transplant and the optimal dosing, timing, and duration of therapy.

Several agents designed to target specific pathways in AML are also being evaluated for posttransplant maintenance. One such target is the tyrosine kinase FMS-like tyrosine kinase 3-internal tandem duplication (FLT3-ITD).[38,44] AML patients positive for FLT3-ITD mutations have been found to have shorter remission times and higher relapse rates than those without these mutations. FLT3 inhibitors, tyrosine kinase inhibitors (TKIs), have been evaluated in several different studies in the setting of posttransplant maintenance.[38,44] First-generation TKIs include sorafenib and midostaurin. Based on a nonrandomized comparison, the Acute Leukemia Working Party of the European Bone Marrow Transplantation (EBMT) Association recommends sorafenib as maintenance therapy after allogeneic HCT.[44] Midostaurin, gilteritinib, and quizartinib are also being evaluated in this setting.[38,40]

Based on their activity in AML and MDS, hypomethylating agents (HMAs) such as 5-azacitidine and decitabine have been evaluated in the posttransplant setting to prevent relapse in these populations but with mixed results.[38,40] Additional studies are ongoing to determine the role of these agents as post-HCT maintenance therapies.

Posttransplant therapy is also being evaluated in patients with multiple myeloma. Lenalidomide has been shown to prolong progression-free survival compared with patients receiving placebo and is now considered standard of care unless contraindicated.[38,45] Unfortunately, a small but significant increased risk of second primary cancers has been reported in the lenalidomide-treated patients. Patients should be informed of this potential safety issue when treatment with lenalidomide after autologous HCT is considered. Bortezomib, a proteasome inhibitor delivered either intravenously or subcutaneously, can be considered for maintenance therapy after autologous HCT. Although some studies suggest bortezomib increases progression-free survival, no prospective randomized trials have been conducted. Its use should be reserved for patients with poor tolerance to lenalidomide, renal insufficiency, high-risk cytogenetics, or history of other cancers.[38] Another proteasome inhibitor, the oral agent ixazomib, has also been reported to improve progression-free survival when used as a post-HCT maintenance therapy.[38] Other agents currently being explored include carfilzomib, daratumumab, and elotuzumab.

TRANSPLANT-RELATED COMPLICATIONS

8 Although many patients with cancer treated with high-dose chemotherapy and autologous or allogeneic HCT experience long-term survival and cure of their disease, this modality is associated with many serious and potentially life-threatening complications. Despite the availability of improved broad-spectrum anti-infective agents, immunosuppressive drugs, and hematopoietic growth factors, the transplant-related mortality rate after allogeneic HCT with HLA-matched sibling and unrelated donors is 20% to 30%. The mortality rate is generally lower with RIC regimens and higher when alternative donors are used. Causes of nonrelapse mortality include regimen-related toxicity, infection, GVHD, or immunosuppression. The risk of transplant-related mortality after autologous HCT generally is less than 5%, depending on the patient population and conditioning regimen. The mortality rate is lower with autologous transplants because of the lack of GVHD and associated complications of immunosuppression. Transplant-related mortality in autologous HCT usually is caused by regimen-related toxicity or infection.

Table e163-1 lists the dose-limiting nonhematologic toxicities for several drugs that are commonly included in MAC regimens. These toxicities may be uncommon or rare with the administration of conventional doses of specific drugs. When these agents are given in high doses, the toxicities seen with conventional doses (eg, mucositis, enteritis, nausea, vomiting, and hematuria) can be more frequent or severe. Several unusual and severe manifestations of HCT regimen-related toxicities are discussed in this section.

Sinusoidal Obstruction Syndrome

Sinusoidal obstruction syndrome (SOS), formerly known as hepatic venoocclusive disease (VOD), occurs as a result of chemotherapy-induced damage to the sinusoidal endothelial cells of the liver, which leads to release of proinflammatory cytokines and further damage to the endothelium. Gaps develop between the endothelial cells, which allow cellular debris to accumulate and cause the sinusoids to narrow and eventually become occluded. In addition, injury to the endothelial cells produces fibrin deposition and clot formation, further narrowing the sinusoids.[46,47] These histologic changes can lead to obstruction of sinusoidal flow, reduced hepatic venous outflow, portal hypertension, and hepatic failure. Clinical signs of SOS include fluid retention (resulting in sudden weight gain and ascites), hepatomegaly (sometimes painful), and hyperbilirubinemia or jaundice. The diagnosis of SOS is based on the revised EBMT criteria which considers the presentation of symptoms and length of time from transplant.[47] SOS occurs within the first 3 weeks after transplant in “classical SOS” or later than 3 weeks in “late-onset SOS,” and the incidence of SOS ranges from 5% to 20% in most published series. Severe SOS is fatal in 50% to 75% of cases. Factors reported to increase the risk of SOS include use of TBI-containing conditioning regimens (dose-dependent), use of sirolimus for the prevention of GVHD, increased systemic exposure to busulfan, oral administration of busulfan, individual variability in cyclophosphamide metabolism, chronic viral hepatitis, and elevated liver function test results before transplant. Pretransplant exposure to either gemtuzumab ozogamicin or inotuzumab ozogamicin have been implicated in the development of SOS in patients undergoing allogeneic HCT, especially when given within a few months of transplant.[46,47]

Ursodiol is the only agent that can reduce the risk of SOS in patients undergoing MAC allogeneic transplants and reduce the risk of transplant-related mortality and GVHD.[47] Defibrotide, a polydisperse oligonucleotide with fibrinolytic properties, can be considered for SOS prophylaxis in patients at high risk of SOS.[47] A prospective randomized confirmatory trial in adults and children has been completed.

Treatment of SOS is generally supportive, including fluid and electrolyte management, platelet transfusions, paracentesis, and pain management.[47] Hepato- and nephrotoxic drugs should be avoided. Mild-to-moderate disease generally resolves without specific therapy. Defibrotide was FDA approved based on prospective clinical trials in patients with SOS with advanced multi-organ dysfunction that showed improved response rates and lower mortality as compared with historical controls.[48] Adverse effects were not distinguishable from those commonly reported in this patient population. Post-hoc analysis showed that earlier initiation of defibrotide treatment was associated with significantly higher posttransplant day 100 survival rates.[49] Future research should focus on identification of biomarkers that predict SOS onset.

Pulmonary Complications

Pulmonary complications after HCT can be categorized as infectious and noninfectious (see Chapter e48). Noninfectious complications can be caused by direct damage to the pulmonary tissue by chemotherapy or radiation used in the conditioning regimen, immune effects of the graft, or other causes not clearly understood. Early complications include diffuse alveolar hemorrhage, periengraftment respiratory distress syndrome, and idiopathic interstitial pneumonitis.[50] Diffuse alveolar hemorrhage is characterized by dyspnea, hypoxia, dry cough, and fever; chest radiography usually shows diffuse infiltrates in an alveolar pattern. It occurs in 5% to 12% of HCT patients with mortality rates reported as high as 60% to 100%. Diffuse alveolar hemorrhage is diagnosed by examination of bronchoalveolar lavage fluid via bronchoscopy, which reveals progressively bloodier fluid with each instilled aliquot and negative findings on microbiologic analysis. Although the condition can be life-threatening or fatal, prompt treatment with high doses of corticosteroids (methylprednisolone 500-1000 mg daily for five days) is sometimes beneficial.[50]

Periengraftment respiratory distress syndrome is characterized by fever, erythrodermatous skin rash, and noncardiogenic pulmonary edema and can occur during neutrophil recovery after HCT.[50] The incidence of engraftment syndrome is not known because of the lack of uniform diagnostic criteria, although some series report that 5% to 10% of patients who receive autologous HCT develop the syndrome. This syndrome can progress to life-threatening respiratory failure with or without multiple organ failure. Treatment consists of methylprednisolone 1 to 2 mg/kg/day for 3 days, followed by a rapid taper.

Idiopathic interstitial pneumonitis (also called idiopathic pneumonia syndrome) is defined as widespread alveolar injury in the absence of active lower respiratory tract infection, cardiac or renal dysfunction, or iatrogenic-induced circulatory overload after HCT.[50] Patients with idiopathic interstitial pneumonitis are clinically indistinguishable from patients with interstitial pneumonitis related to infection. Idiopathic interstitial pneumonitis is postulated to have a multifactorial etiology, including toxic effects of MAC regimens, immunologic cell-mediated injury, inflammatory cytokine-induced lung damage, and occult pulmonary infections. The risk is similar in recipients of autologous or allogeneic HCT but appears to be higher in patients who are conditioned with a TBI-containing regimen or who have acute GVHD. A mortality rate as high as 80% has been reported, and treatment consists of supportive care and broad-spectrum antimicrobial therapy; the efficacy of corticosteroids has not been consistently reported.

Late pulmonary complications cover a wide spectrum of disorders and include both obstructive and restrictive lung diseases.[50,51] The most common disorders are cryptogenic organizing pneumonia (COP; previously known as bronchiolitis obliterans with organizing pneumonia [BOOP]) and bronchiolitis obliterans syndrome (BOS). COP is an interstitial and airspace disease with symptoms that mimic classic pneumonia, but biopsy reveals chronic alveolar inflammation and extensive granulation of the alveolar ducts and small airways.[50] COP is generally responsive to prednisone 1 mg/kg/day with an extended taper over several months. BOS is thought to result from chronic GVHD affecting the lungs and is generally irreversible with mortality rates as high as 40%.[50,51] Therapy consists of oral corticosteroids, which are about 50% effective, often in combination with the triple-therapy inhaled fluticasone, azithromycin, and montelukast (FAM). Extracorporeal photopheresis may also provide benefit.[50,51]

Graft Failure

Initial engraftment of hematopoietic cells after MAC regimens usually occurs in the first 2 to 4 weeks after transplant. Engraftment is evidenced by rising peripheral blood counts and the presence of hematopoietic precursor cells in the marrow; it is defined as an absolute neutrophil count of greater than 500 cells/mm^3 (0.5 × 10^9/L) and a platelet count of greater than 20,000 cells/mm^3 (20 × 10^9/L) on the first day of 7 consecutive days without a platelet transfusion. In allogeneic HCT, the presence of donor cells (ie, chimerism) is confirmed by PCR-based analysis of polymorphic DNA sequences of cells from the bone marrow and peripheral T cells. Full chimerism is defined as greater than 95% of cells of donor origin. In most patients, engraftment is sustained with complete recovery of hematopoiesis.[35]

However, graft failure (loss of bone marrow function with resulting loss in peripheral blood counts) can occur after both allogeneic and autologous HCT.[52,53] It can be the result of heavy pretreatment with chemotherapy or radiation therapy (or both); infusion of insufficient numbers of hematopoietic stem cells; viral infection; recurrence of primary hematologic malignancy; drug reaction (eg, ganciclovir); development of a secondary myelodysplasia; or in the allogeneic setting, an immunologic reaction between the donor and recipient caused by inadequate immunosuppression of the recipient (ie, graft rejection). Two syndromes have been observed. Whereas early graft failure occurs when the rate of hematopoietic recovery is delayed greater than 28 days after transplant (later after UCBT) or does not occur at all (primary graft failure or delayed engraftment), late graft failure is characterized by a decline in peripheral blood counts after initial engraftment (secondary graft failure).[35] With widespread use of PBSCs and posttransplant growth factors, primary graft failure is rare after autologous and HLA-matched allogeneic HCT but is not uncommon after UCBT. Graft failure that occurs after allogeneic HCT, characterized by regrowth of immunocompetent recipient cells and a simultaneous loss of donor cells, is referred to as *graft rejection*. Graft rejection occurs rarely after HLA-matched allogeneic HCT. An increased risk of graft rejection has been observed in recipients of hematopoietic stem cells from HLA-mismatched donors, recipients of T cell–depleted marrow, and patients with severe aplastic anemia or other nonmalignant disorders. In a large retrospective analysis of over 20,000 patients undergoing myeloablative allogeneic HCT, the incidence of primary graft failure was 5.5%.[53] In this analysis, risk factors for primary graft failure included bone marrow (vs peripheral blood) grafts, RIC regimens, diagnosis of a myeloproliferative disorder, HLA mismatched transplants, ABO incompatibility, and BuCy conditioning (compared with other MAC regimens).

The long-term prognosis of patients with persistent graft failure is poor. Despite supportive care and treatment with hematopoietic growth factors, death may result from infection or bleeding. In some patients with an allogeneic donor, a second infusion of stem cells can be attempted. While this can be a viable alternative for some patients, many are not physically able to undergo a second transplant. Of those that do, nonrelapse mortality is high, despite the use of NMA regimens.[52] Hematopoietic growth factors usually are given after transplant to patients who receive autologous HCT, based on several benefits associated with their use including fewer antibiotic days and decreased length of stay. Decreasing resource utilization after transplant (total antibiotic days and length of stay) can help justify the cost of growth factors in this patient population. Growth factors can be initiated the day of, the day after, or as late as 7 days after the infusion of stem cells and are continued until neutrophil recovery to greater than an arbitrary number of neutrophils (500-1,000 cells/mm^3 [$0.5 - 1.0 \times 10^9$/L]). Pegfilgrastim appears to be equally efficacious to G-CSF in this setting.

Hematopoietic growth factors also accelerate the rate of neutrophil recovery in patients undergoing allogeneic HCT. However, G-CSF has not been shown to reduce infection rates, antibiotic days or length of stay in this population. The decision to use G-CSF preemptively may be reserved for patients who are at risk for delayed neutrophil recovery (eg, UCBT or those receiving PTCy). If allogeneic HCT patients develop graft failure, G-CSF can be given based on data that supports its use in this situation.[52]

Results of studies to improve platelet recovery posttransplant with thrombopoietin and interleukin-11 (IL-11) have been disappointing. Several case studies and case series have described the use of eltrombopag, an oral thrombopoietin receptor agonist, in allogeneic HCT patients with persistent thrombocytopenia posttransplant.[52] Although additional data are needed, the response rates have been promising. Platelet transfusions remain the standard of care in patients with thrombocytopenia below a given threshold (eg, 10,000 cells/mm^3 [10×10^9/L]) and in patients with significant bleeding.

Anemia may be problematic in the posttransplant setting, especially in patients receiving allogeneic HCT. The etiology is unclear and most likely is multifactorial. Although erythropoiesis-stimulating agents may reduce the need for red blood cell transfusions, its use in cancer patients is associated with an increased risk of adverse events and is limited by FDA warnings and restrictions.

Graft-Versus-Host Disease

GVHD is caused by immunocompetent allogeneic donor T cells reacting against recipient/host antigens on the surface of antigen-presenting cells (APCs). In that setting, donor T cells recognize unmatched major or minor histocompatibility antigens of the host as genetically foreign, become activated, proliferate, and attack recipient tissue, thereby producing the clinical syndrome of GVHD.

Two different clinical syndromes of GVHD (acute and chronic) are recognized, each with two subcategories. Classic acute GVHD occurs within 100 days after transplant or DLI while persistent, recurrent or late-onset acute GVHD occurs beyond 100 days after transplant, withdrawal of immunosuppression or DLI.[54] Both subcategories of acute GVHD occur in the absence of chronic GVHD. Classic chronic GVHD usually occurs after day 100, with only clinical manifestations that can be attributed to chronic GVHD. Chronic GVHD may occur after the resolution of acute GVHD or de novo (no prior acute GVHD). Acute and chronic overlap syndrome is a newly defined entity in which features of both acute and chronic GVHD appear together. Chronic GVHD usually develops before the resolution of acute GVHD (also called progressive onset). The clinical manifestations of GVHD are distinct. Whereas acute GVHD usually is limited to the gastrointestinal tract, skin, and liver, signs and symptoms of chronic GVHD resemble an autoimmune disorder and can affect many organ systems.

A “hyperacute” form of GVHD may occur in patients with multiple HLA mismatches and in patients who receive T cell–replete transplants without adequate GVHD prophylaxis, especially after MAC regimens.[54] Descriptions of hyperacute GVHD vary but usually include fever, generalized erythroderma, desquamation, and edema. More severe forms with accompanying organ failure have been seen in haploidentical donors. Hyperacute GVHD typically occurs about 1 week after transplant before engraftment of neutrophils. The response rate to first-line therapy appears to be lower in patients with hyperacute GVHD compared with patients who develop GVHD later after transplant, but no difference in survival has been observed.

Acute Graft-Versus-Host Disease

The pathophysiology of acute GVHD is a complex inflammatory cascade of innate immune cells (such as neutrophils, macrophages, and monocytes), cytokines, and chemokines.[55,56] The conditioning regimen damages gastrointestinal tissue, weakening the cellular barriers and destroying cells. This permits bacterial translocation from the intestinal lumen into circulation. Invading bacteria release molecules such as lipopolysaccharide, which stimulate neutrophil, monocytes, and dendritic cells. Simultaneously, damaged gastrointestinal cells release additional substances which further enhance inflammation. When the innate immune cells arrive to the site of damage, they act to kill the bacteria by releasing reactive oxygen species (ROS), which adds further damage to recipient GI tissue. Neutrophils and both donor and recipient dendritic cells, also called APCs, activate donor T cells.

Damage to the intestinal mucosa stimulates the secretion of inflammatory cytokines such as IL-1, IL-6 and tumor necrosis factor-α (TNF-α). These cytokines upregulate MHC gene products and host APCs. Activated donor T cells also secrete cytokines such as IL-2 and interferon-γ, contributing to the recruitment of macrophages and alteration of target cells in the gastrointestinal tract and skin so that they are more susceptible to damage. Multiple cytotoxic effector cells (T cells and macrophages) are generated and contribute to target tissue injury by secreting more inflammatory cytokines that cause target cell apoptosis. The term “cytokine storm” is sometimes used to describe the critical role of inflammatory cytokines in this process.

Three general approaches have been used to prevent GVHD in humans. The first is to reduce host tissue damage with the use of RIC regimens. The second and most widely used approach is to modulate donor T cells by reducing T-cell numbers (T-cell depletion), activation (most immunosuppressive agents), or proliferation (antiproliferative agents). The third approach is to block inflammatory stimulation and effectors (eg, TNF-α inhibition, IL-1 receptor blockade).

The principal target organs in acute GVHD are the skin, liver, and gastrointestinal tract.[54] Acute GVHD is classified into four grades, depending on the number of organs involved and the degree of involvement of each organ. Diagnostic criteria from the Mount Sinai Acute GVHD International Consortium (MAGIC) group are outlined in Table e163-2.[57] Grade I disease involves only the skin. Grades II through IV involve the skin and the liver, gastrointestinal tract, or both. Acute skin GVHD usually is manifested as a generalized maculopapular rash that initially involves the face, ears, palms, soles, and upper trunk. The skin rash can spread to the rest of the body and, if untreated or refractory to treatment, will progress to bullae formation and desquamation similar to a burn injury. Gastrointestinal GVHD presents as secretory diarrhea but may progress to abdominal pain or cramping and ileus; hemorrhage may also occur. GVHD of the upper intestinal tract appears as persistent nausea, vomiting, anorexia, and dyspepsia. The diagnosis of gastrointestinal GVHD should be made by biopsy of the intestinal tract (stomach, duodenum, or rectum). Hepatic GVHD usually is asymptomatic, consisting of hyperbilirubinemia and elevated alkaline phosphatase levels; increases in serum transaminases occur less consistently. The diagnosis can be made by biopsy, if possible. Electronic tools or algorithm-driven mobile applications (Apps), such as the ASTCT Practice Guidelines Mobile App, can be easily and freely downloaded on mobile devices to aid in a more accurate assessment and grading of acute GVHD.

TABLE e163-2

Consensus Grading of Acute Graft-Versus-Host Disease

	Organ/Extent of Involvement		
	Skin	**Liver**	**Intestinal Tract**
Stage			
1	Rash on <25% of skin[a]	Bilirubin 2-3 mg/dL (34.2-51.3 μmol/L)[b]	Diarrhea >500-999 mL/day[c] or 3-4 episodes/day; persistent anorexia, nausea, or vomiting[d]
2	Rash on 25%-50% of skin	Bilirubin 3.1-6 mg/dL (51.3-102.6 μmol/L)	Diarrhea >1,000-1,500 mL/day or 5-7 episodes/day
3	Rash on >50% of skin	Bilirubin 6.1-15 mg/dL (102.6-256.5 μmol/L)	Diarrhea >1,500 mL/day or >7 episodes/day
4	Generalized erythroderma with bulla formation and desquamation (5% of body surface area)	Bilirubin >15 mg/dL (256.5 μmol/L)	Severe abdominal pain with or without ileus or grossly bloody stools (regardless of stool volume)
Grade			
0	None	None	None
I	Stage 1-2	None	None
II	Stage 3	and/or Stage 1	and/or Stage 1
III[e]	—	Stage 2-3	and/or Stage 2-3
IV[f]	Stage 4	or Stage 4	or Stage 4

Data from Reference 57.

[a] Use the “rule of nines” to determine body surface area involvement.

[b] Range given as total bilirubin. Downgrade one stage if an additional cause of elevated bilirubin has been documented.

[c] Volume of diarrhea applies to adults. For pediatric patients, the volume of diarrhea should be based on body surface area.

[d] Persistent nausea with histologic evidence of graft-versus-host disease in the stomach or duodenum.

[e] Grade 0-3 skin may also be present but overall grade driven by liver or GI involvement

[f] Grade IV may include lesser organ involvement but with extreme decrease in performance status.

The overall incidence of moderate-to-severe (grades II-IV) acute GVHD varies widely depending on patient- and transplant-related characteristics. The incidence of GVHD is related to the degree of histocompatibility, number of T cells in the graft, donor and recipient age and gender, intensity of the conditioning regimen, source of hematopoietic cells (bone marrow versus peripheral blood), and prophylactic regimen. The most severe acute GVHD is observed in allogeneic HCT with non-HLA-identical donors. In this setting, the incidence of grades II to IV acute GVHD can exceed 50% despite aggressive GVHD prophylaxis. Severe acute GVHD is a major cause of mortality, and the risk of death increases as the grade of GVHD increases. This risk is further increased if initial therapy is not effective.

Multiorgan acute GVHD and the drugs given to prevent or treat the disease are associated with delayed immunologic recovery and increased susceptibility to infections. Infection is often the primary cause of death in patients with GVHD. Patients with GVHD treated with an immunosuppressive regimen should receive prophylactic antiviral, antibacterial, and antifungal therapies and be monitored routinely for the occurrence of these infections.

As outcomes from acute GVHD can be potentially life threatening, identifying which patients will have poor outcomes would be beneficial. This has led to an interest in identifying GVHD biomarkers, defined by the Food and Drug Administration (FDA) as “an indicator of normal biological processes, pathogenic processes, or responses to an exposure or intervention, including therapeutic interventions.” In this setting, biomarkers for acute GVHD are now designated as one of four types: diagnostic (identifies acute GVHD at early onset; distinguishes it from similar disease presentations), prognostic (determines risk and severity of acute GVHD), predictive (provides insight into how a patient may respond to a specific therapy), or response to treatment (helps to monitor response once therapy has been started).[58] While several biomarkers have been discovered and continue to be studied, two have been successfully tested and validated in several studies: stimulation 2 (ST2) and regenerating islet-derived 3-alpha (REG3α). Either can be used individually or together; both fall under all four biomarker subtypes. Presence or absence of these markers can be used to guide or support the care of acute GVHD in transplant recipients.

Prevention of Acute Graft-Versus-Host Disease

⑨ Because treatment of established acute GVHD often is unsatisfactory, aggressive preventive measures usually are taken. The most common strategy used to prevent acute GVHD is to block the activation of T cells by administration of immunosuppressive agents.[55,56] Several immunosuppressive agents have been used, including methotrexate (MTX), cyclosporine (CSA), tacrolimus (TAC), sirolimus, mycophenolate mofetil (MMF), PTCy, ATG, abatacept, corticosteroids, and monoclonal antibodies directed at T cells. Table e163-3 shows the doses, toxicities, and monitoring of immunosuppressive agents used to prevent or treat GVHD.[59–66] Most GVHD prophylaxis regimens combine immunosuppressive agents that affect different stages of T-cell activation. The most commonly used GVHD prophylaxis regimens are CSA or TAC with MTX; both combinations are considered equivalent. Another strategy is removing or depleting most T cells from donor bone marrow ex vivo before transplant by physical separation or by treatment with monoclonal antibodies directed at T cells.

TABLE e163-3

Immunosuppression for the Prevention and Treatment of GVHD

Agent	Dose	Drug Monitoring
Prevention		
Tacrolimus (TAC)[59]	0.02-0.03 mg/kg/day (IBW) IV beginning 1-3 days before transplant; change to PO when able to tolerate	Check blood levels ~72 hours after start and then 2-3 times/week until stable (trough blood levels, 5-15 μg/L [6.2-18.6 nmol/L]); serum creatinine for renal toxicity; CBC for hematologic toxicity; CMP, CBC, haptoglobin for TMA; blood pressure for hypertension; BMP for electrolyte abnormalities
Cyclosporine (CSA)[59]	3-5 mg/kg/day (IBW) IV beginning 1-3 days before transplant; change to PO when able to tolerate	Check blood levels ~72 hours after start and then 2-3 times/week until stable (trough blood levels, 150-450 mcg/L [125-374 nmol/L]); serum creatinine for renal toxicity; CBC for hematologic toxicity; CMP, CBC, haptoglobin for TMA; blood pressure for hypertension; BMP for electrolyte abnormalities
Sirolimus[60]	Loading dose 12 mg PO on day +1 followed by 4 mg	Check serum levels ~24 hours after start and then 2-3 times/week until stable (trough serum levels, 3-12 ng/mL [3-13 nmol/L]); serum creatinine for renal toxicity; CBC for hematologic toxicity;

	PO daily starting on day +2	LFTs for liver toxicity
Methotrexate (MTX)[59,60]	15 mg/m^2 IV on day +1 followed by 10 mg/m^2 IV on days +3, 6, and 11	Monitor for toxicity: mucositis; LFTs for hepatic dysfunction; serum creatinine for renal impairment; fluid retention; and CBC for hematologic toxicity; methotrexate levels are not routinely monitored unless the patient develops renal dysfunction or third spacing; doses may be omitted if severe mucositis or hepatotoxicity develops; leucovorin may be administered to reduce toxicity
	or	
	5 mg/m^2 IV on days +1, 3, 6, and 11	
Mycophenolate mofetil (MMF)[59,60]	15 mg/kg/dose IV twice daily (maximum dose, 3 g/day) beginning on day 0; change to PO when able to tolerate	Monitor for toxicity: CBC for neutropenia; severe GI symptoms may occur; therapeutic drug monitoring can be considered (more routine in pediatric population)
Cyclophosphamide (Cy)[60]	50 mg/kg/day (IBW) IV on days +3 and +4	Monitor for toxicity: BMP for renal impairment or SIADH; LFTs for hepatic toxicity (including SOS); urinalysis for hemorrhagic cystitis; vital signs and possible cardiac workup for pericarditis (only for symptomatic patients). Mesna must be administered around cyclophosphamide administration to prevent hemorrhagic cystitis
Rabbit ATG[60,61]	2.5-6 mg/kg/day IV beginning 3 days before transplant	Monitor for toxicity: infusion reactions, frequent vital signs during infusion, fever, rash, cardiovascular and GI dysfunction, anaphylaxis; serum sickness
Alemtuzumab[60]	10-20 mg/day IV daily beginning 4-5 days before transplant	Monitor for toxicity: fever, chills, infection, and anaphylaxis
Abatacept[60]	10 mg/kg/dose IV on days -1, +5, +14, +28	Monitor for fever, infection, neutropenia; CMV, EBV
Treatment		
Methylprednisolone[a,b]	0.5-2 mg/kg/day	Monitor for toxicity: glucose for hyperglycemia, blood pressure for hypertension; labile mood; bone osteopenia, avascular bone necrosis; impaired wound healing; adrenal insufficiency
or		
Prednisone[a,b,18,62]		
Ruxolitinib[b][18,63,64]	Acute GVHD: 5 mg PO BID with option to increase to 10 mg PO twice daily after 3 days in the absence of cytopenia	Monitor CBC for anemia, thrombocytopenia, and neutropenia; infections such as CMV
	Chronic GVHD: 10 mg PO BID	

Mycophenolate mofetil (MMF)[18,62]	1.5-2 g PO daily in divided doses	As above
Sirolimus[18,62]	1-2 mg/day; then adjust based on levels	As above
Infliximab[18,65]	10 mg/kg/week for at least four doses	Monitor for toxicity: anaphylaxis (rare)
Etanercept[18,65]	0.4 mg/kg/dose (maximum dose, 25 mg) SC twice weekly for 8 weeks	Monitor for toxicity; generally well tolerated
Rabbit ATG[18,62]	0.5 mg/kg for first dose followed by 1-1.5 mg/kg for subsequent doses	As above
Belumosudil[18,66]	200 mg PO daily	Monitor for upper respiratory infections; diarrhea, nausea; edema, hypertension; increased LFTs
Ibrutinib[c][18,67]	420 mg PO daily	Monitor for fatigue; diarrhea; bleeding, bruising

ATG, anti-thymocyte globulin; BID, twice daily; BMP, basic metabolic panel; CBC, complete blood count; CMP, complete metabolic panel; CMV, cytomegalovirus; EBV, Epstein-Barr Virus; ECP, extra-corporal photopheresis; GI, gastrointestinal; IBW, ideal body weight; IV, intravenous; LFT, liver function test; PO, orally; SC, subcutaneous; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; SOS, sinusoidal obstruction syndrome; TMA, thrombotic microangiopathy.

[a] Considered first-line therapy for both acute and chronic GVHD (initial dose varies per indication).

[b] Treatment for both acute and chronic GVHD.

[c] Treatment for only chronic GVHD.

The combination of a calcineurin inhibitor (either CSA or TAC) with MTX is considered the standard immunosuppressive regimen for the prevention of acute GVHD. Intravenous CSA or TAC is usually started a few days before or on the day of transplant. Patients are converted to oral formulations when they can be tolerated. CSA or TAC is usually given at full doses until days 50 to 100, gradually tapered in the absence of GVHD and discontinued by day 180. MTX is given IV on days 1, 3, 6, and 11 after transplant. Elimination of one or more MTX doses may be associated with an increased risk of GVHD. However, toxicities such as severe mucositis, delayed engraftment, hepatotoxicity, or the development of conditions that may prolong MTX systemic exposure (eg, renal failure or third spacing) are common reasons to omit the day 11 dose of MTX. For patients who have delayed MTX elimination or experience significant MTX toxicity, monitoring of MTX levels with leucovorin rescue may be warranted.

Despite standard prophylaxis with CSA or TAC and MTX, grade II to IV acute GVHD still occurs in 30% to 50% undergoing allogeneic HCT.[55] In search of less toxic agents and more effective combinations, other prophylactic regimens have been evaluated. Sirolimus, an mTOR inhibitor, has theoretical advantages when used as GVHD prophylaxis. This agent has been reported to promote immune tolerance through generation of regulatory T cells, has antiviral properties (CMV and Epstein-Barr virus), and has antitumor activity against some hematologic malignancies.[60] Several studies have shown encouraging results with sirolimus when combined with a calcineurin inhibitor (TAC or CSA) in the prevention of acute GVHD, and many clinicians believe that the combination of TAC and sirolimus is less toxic and more efficacious than CSA and sirolimus. A meta-analysis of sirolimus-based GVHD prophylaxis showed that when compared to TAC and either MTX or MMF, sirolimus-based regimens significantly decreased the incidence of grade II-IV acute GVHD (relative risk 0.65). However, the incidence of grade III to IV acute and chronic GVHD was similar, and no significant differences in event-free or overall survival were observed. An analysis of the sirolimus toxicity showed a significantly higher risk of SOS.[68] Because of the association observed with SOS, sirolimus should not be used in patients who are at increased risk for SOS due to baseline characteristics or their HCT conditioning regimen.

Other MTX-sparing strategies have been evaluated for GVHD prophylaxis. Mycophenolate mofetil (MMF) through its metabolite, mycophenolic acid, inhibits lymphocyte proliferation and is synergistic with calcineurin inhibitors. MMF, combined with either CSA or TAC, is a reasonable alternative to MTX when toxicity is a concern, although anti-GVHD activity may be inferior. In recipients of UCBT, MMF is often used to prevent delayed engraftment associated with MTX.[59,62]

PTCy is another GVHD prophylaxis strategy used for acute GVHD prevention and is given either as a single agent, in combination with sirolimus, or in combination with two other agents (sirolimus or TAC, plus MMF).[60] Initially established in the setting of haplo-HCT, PTCy is now being used in matched related, unrelated, and mismatched unrelated HCTs.[69,70] Its immunosuppressive activity is related to its antiproliferative effects on rapidly dividing alloreactive T cells. Hematopoietic stem cells have high levels of aldehyde dehydrogenase, which spares them from the antiproliferative activity of cyclophosphamide. The use of PTCy, combined with other immunosuppressive agents such as MMF and a calcineurin inhibitor, is an effective immunosuppressive regimen. In a phase II multicenter trial (BMT CTN 1203), 273 patients undergoing allogeneic HCT with RIC were randomized to PTCy, TAC, and MMF and two other GVHD prophylaxis regimens; each of the three regimens was compared to a concurrent nonrandomized prospective cohort of 224 patients receiving standard GVHD prophylaxis with TAC and MTX.[71] When compared to the control group, the PTCy combination had a higher one-year GVHD-free, relapse-free survival (primary endpoint) and lower risk of grade III-IV acute GVHD and chronic GVHD requiring intervention. Disease relapse and survival rates were similar.[71] Given the positive results shown with the PTCy combination, a multicenter phase III trial is underway to determine the efficacy of this three-drug regimen over the historic standard.[69]

Abatacept, a recombinant fusion protein that blocks the costimulatory CD28-CD80/86 interaction and inhibits T cell proliferation, is FDA approved for the prevention of GVHD. FDA approval was based on a phase II trial in which patients were placed into one of two strata based on whether they were recipients of HLA-matched or mismatched unrelated donor HCT.[72] Patients undergoing matched unrelated donor HCT were randomized to receive standard GVHD prophylaxis (calcineurin inhibitor and MTX) with abatacept or placebo. Patients undergoing HLA-mismatched unrelated donor HCT received a calcineurin inhibitor, MTX, and abatacept and were compared to a CIBMTR control group of patients who received standard GVHD prophylaxis with a calcineurin inhibitor and MTX. In patients undergoing HLA-matched related donor HCT, the incidence of grades III and IV acute GVHD was lower in the patients receiving the abatacept combination, but the difference was not statistically significant. However, the risk of grades III and IV acute GVHD was significantly lower in patients undergoing HLA-mismatched unrelated donor HCT. No significant difference in the risk of chronic GVHD between groups was observed with either strata.[72] Other agents such as bortezomib and tocilizumab have been studied in GVHD prevention, but only limited efficacy has been observed and their use is not recommended outside of a clinical trial.[60]

Another strategy to prevent acute GVHD is to reduce the number of donor T cells in the stem cell donation. In vivo T-cell depletion may be incorporated into conditioning regimens with agents such as ATG. Results from randomized trials show that ATG decreases the incidence of chronic GVHD without increasing the risk of relapse or nonrelapse mortality; a reduction in acute GVHD was not consistently reported.[60,61] Results from these trials are difficult to compare due to the heterogeneity in ATG products, dosage and schedule, donor, conditioning, and other agents used for GVHD prophylaxis. Most of these studies were unable to demonstrate significant differences in overall survival, despite the lower incidence of chronic GVHD.[60] Based on the results of these studies, the EBMT suggest that rabbit ATG should be used in patients undergoing matched unrelated donor HCT and in patients undergoing matched related donor HCT who are at high risk for GVHD.[62] These recommendations have not been widely adopted in the United States.

Treatment of Acute Graft-Versus-Host Disease

⑩ Patients with mild skin-only acute GVHD (grade I) can be treated with topical corticosteroid preparations and counseled on the appropriate use of sunscreen. If a patient develops grades II to IV GVHD, prophylactic agents are continued, and single agent, high-dose corticosteroids in the form of IV methylprednisolone or oral prednisone are given.[18,62,65,73] The usual dosage is 0.5 to 2 mg/kg/day given in two divided doses; higher dosages have not been shown to be more efficacious. About 25% to 40% of patients with established acute GVHD respond to high-dose corticosteroids. If the patient responds, the corticosteroid dose is tapered gradually, depending on response. In patients who experience a flare in GVHD during the taper phase, therapy consists of increasing the corticosteroid dose and then tapering more slowly. Steroid-sparing options such as sirolimus have also been evaluated and may provide an effective steroid-free therapy in select patients with lower risk acute GVHD (defined by biomarker assessment).[65] Oral beclomethasone dipropionate, a topically active corticosteroid, has been shown to reduce the frequency of gastrointestinal GVHD relapses when continued after prednisone taper.[62,74] Administration of beclomethasone has been associated with improved survival at 200 days and 1 year after transplant. Budesonide, another nonabsorbable corticosteroid, has also been evaluated in uncontrolled studies and may also reduce the need for sustained use of high-dose systemic corticosteroid administration.[62,74]

GVHD-associated mortality is strongly correlated to response to initial treatment with corticosteroids and ranges from about 25% in patients who had a complete response to about 80% in patients who had no response or progressive disease. The mortality rate of patients with steroid-refractory acute GVHD is high: 50% at 6 months and less than 30% at 2 years.[73] Criteria and indications for initiating secondary therapy for steroid-refractory acute GVHD are not well defined. Although different centers may have varying criteria, in general, if the manifestations of acute GVHD in any organ worsen over 3 days of corticosteroid treatment or symptoms do not improve by 7 days, the patient likely will not respond to corticosteroids, and secondary therapy should be considered.[65] Several therapies have been evaluated in steroid-refractory acute GVHD. Ruxolitinib is an oral FDA-approved therapy for steroid-refractory acute GVHD that inhibits both Janus kinase (JAK) 1 and JAK 2, tyrosine kinases that have been found to be associated with acute GVHD pathogenesis. When given in steroid-refractory patients, ruxolitinib not only improves the overall response rate but also allows steroid doses to be reduced significantly in many patients.[63,65,74] Other options for second-line therapy consist of continuation of corticosteroids with the addition of one or more of the following: ATG, tocilizumab, mycophenolate mofetil, sirolimus, infliximab, etanercept, alemtuzumab, or pentostatin.[18,62,65] One approach that has shown benefit in this setting is extracorporeal photopheresis (ECP). During this procedure, the patient's blood is exposed extracorporeally to 8-methoxypsoralen followed by ultraviolet A radiation and then returned to the patient. This process results in suppression of T-cell reactivity and induction of regulatory T cells. Clinical results have been positive, especially in patients with skin GVHD.[75] The choice of a second-line regimen for acute GVHD should be based on the risk of potential toxicities, interactions with other agents, convenience, and cost.

Chronic Graft-Versus-Host Disease

Chronic GVHD is the major determinant of late transplant-related morbidity and mortality in allogeneic transplant recipients. The pathophysiology of chronic GVHD appears to involve defects in immune tolerance combined with adaptive immune responses targeting autoantigens. This produces chronic tissue inflammation and damage, often resulting in fibrosis.[76,77] A three-phase model based on murine and human data has been proposed to explain the pathophysiology of chronic GVHD: tissue injury and inflammation secondary to a variety of insults (eg, conditioning regimen toxicity, infection, acute GVHD, sun exposure) (phase 1), chronic inflammation and dysregulated B-cell and T-cell immunity (phase 2), and tissue repair with fibrosis (phase 3).[77] Specific cellular and cytokine activity during these processes have become therapeutic targets for which pharmacologic agents are being evaluated and used in the prevention and treatment of chronic GVHD.

The incidence of chronic GVHD ranges from 30% to 70% and is increasing due to the increased use of alternative (mismatched and unrelated) donors, transplantation of older patients, and longer survival of transplant recipients. The risk of chronic GVHD increases with a previous history of acute GVHD, increasing donor and recipient age, patients who receive transplants from HLA-nonidentical donors and in patients who receive PBSC transplants versus BMT (especially with higher $CD34^+$ cell doses).[77] Prophylaxis of chronic GVHD includes similar strategies used to prevent acute GVHD such as in vivo T-cell depletion with ATG or PTCy.[76,78]

Unlike the acute form, chronic GVHD can affect many different organs and tissues including the skin, mouth, eyes, genitalia, GI tract, liver, lung, and joints.[77] The National Institutes of Health (NIH) Consensus Development Project developed standardized criteria for the diagnosis of chronic GVHD and proposed a clinical scoring system for the evaluation of patients with chronic GVHD based on the extent of organ damage and degree of functional impairment.[79] The Working Group recommends that the diagnosis of chronic GVHD be made with the presence of at least one diagnostic clinical sign of chronic GVHD (eg, poikiloderma or esophageal web) or a distinctive manifestation (eg, keratoconjunctivitis sicca) confirmed by biopsy or other test (eg, Schirmer test). In addition, the NIH Working Group recommends documenting all specific manifestations (acute and chronic) when establishing a diagnosis.[79]

The clinical scoring system categorizes chronic GVHD into mild, moderate, and severe, based on the scoring of individually involved organ systems.[79] Mild chronic GVHD involves only one or two organs or sites (except the lung) with no clinically significant functional impairment (no more than mild involvement in any one organ). Moderate chronic GVHD involves at least one organ or site with clinically significant but no major disability (at least moderate involvement), three or more organs or sites with no clinically significant functional impairment (no more than mild involvement), or mild lung involvement. Severe chronic GVHD indicates major disability caused by chronic GVHD (at least one organ with severe involvement) or at least moderate lung involvement.

Patients with mild skin-only chronic GVHD can be treated with topical steroid preparations; lower potency steroids are preferred for the face, axillae, and groin whereas more potent preparations can be used for other areas. Topical calcineurin inhibitor products such as TAC and pimecrolimus have also been used with some success.[18,80] Mild-to-moderate involvement of the mouth can also be managed with local therapy including rinsing with oral solutions of high potency steroids such as dexamethasone, budesonide, or clobetasol.[18,80] Artificial tears are usually recommended for mild ocular involvement; moderate-to-severe disease requires CSA or steroid eye drops or punctal occlusion.[80]

Initial treatment of patients with moderate or severe chronic GVHD consists of prednisone 0.5 to 1 mg/kg/day with or without either sirolimus or a calcineurin inhibitor.[18,78] Although sirolimus and calcineurin inhibitors do not clearly improve the response rates to prednisone, they are often used to reduce toxicities of prolonged steroid therapy by enabling the use of lower prednisone doses, especially in patients who may be at high risk for prednisone-related complications. The addition of other agents such as MMF to first-line treatment with prednisone has not been shown to be beneficial.[76,78] Tapering of prednisone dosing is generally initiated after 1 to 2 weeks if signs and symptoms have improved or stabilized. The tapering schedule varies by institution. Unfortunately, patients with chronic GVHD may require many lines of therapy and often continue prolonged immunosuppressive treatment for several years from the initial diagnosis.[78]

In addition to treatment specifically for chronic GVHD, ancillary therapies and supportive care should be recommended to lessen the symptoms of chronic GVHD.[80,81] Patients should be educated on the avoidance of sun exposure and the use of sunscreens to reduce skin injury and exacerbation of GVHD skin lesions. Nonsclerotic skin lesions without erosions or ulcerations may respond well to emollients in addition to topical steroids. Patients should be advised to maintain good oral hygiene with routine dental care. Saliva substitutes can be given for mild dry mouth symptoms. Physical therapy is recommended to reduce functional loss from steroid myopathy, joint contractures, and deconditioning.[80]

About one-third of patients respond to initial systemic steroid therapy; those who do not respond have a poor prognosis. Steroid-refractory chronic GVHD is defined as progression on 1 mg/kg/day for 2 weeks, stable disease on greater than or equal to 0.5 mg/kg/day of prednisone for 4 to 8 weeks, or inability to taper prednisone to less than 0.5 mg/kg/day due to a flare in symptoms. Patients with steroid-refractory disease require additional therapy to control progression and reduce systemic steroid exposure. Uncontrolled trials have investigated several therapies in this setting with varying degrees of success. No consensus has been reached regarding the optimal choice for salvage therapy.[18,76–78,81,82] When choosing initial salvage therapy, clinicians should consider agents with documented activity and an adequate safety profile as well as agents that are steroid sparing. To date, three agents have received FDA approval for the treatment of steroid-refractory chronic GVHD: ibrutinib, belumosudil, and ruxolitinib.[83] Several other agents have reported activity in refractory chronic GVHD including extracorporeal photophoresis, sirolimus, methotrexate, bortezomib, rituximab, low-dose interleukin-2, imatinib, and others.[18,76–78,81,82] Some appear to be more effective in treating specific organ systems better than others. In general, ineffective therapies should be discontinued prior to starting a new agent, except for steroid therapy, which is usually continued. Clinicians are encouraged to enroll patients with steroid-refractory chronic GVHD in clinical trials when available.

Monitoring for long-term drug toxicities and infectious complications is critical during prolonged immunosuppression. Infection is the primary cause of death in patients with chronic GVHD, and antimicrobial prophylaxis is an important component of the care of patients being treated for chronic GVHD. Patients should receive oral trimethoprim–sulfamethoxazole, penicillin, an antifungal azole agent, and acyclovir to prevent infections commonly seen in immunocompromised patients. Routine monitoring for CMV reactivation should be performed. Some HCT centers also administer intravenous immunoglobulin to patients with low serum immunoglobulin G levels. Patients who remain on long-term steroids should be monitored for chronic corticosteroid toxicities, including osteoporosis, cataracts, hypertension, myopathies, and diabetes mellitus. Other chronic GVHD therapies have their own toxicity profiles and patients should be counseled and monitored accordingly.

Infection

Patients undergoing high-dose chemotherapy with autologous or allogeneic HCT are severely immunocompromised and therefore are at high risk for bacterial, fungal, and viral infections. Management of these infections is discussed in detail in Chapters 144 and 145.

Late Complications

With the success of HCT, the number of long-term survivors has grown. Many survivors experience delayed complications of transplantation and treatments used to prevent or treat those complications, including restrictive and obstructive pulmonary disease, bone and joint disease (including osteoporosis and avascular necrosis), cataract formation, endocrine dysfunction (including sterility and thyroid dysfunction), impaired growth and development, infections, cardiovascular disease, chronic renal and hepatic dysfunction, and secondary malignancies.[84,85] These effects are more frequent after allogeneic compared with autologous HCT and among allogeneic HCT patients, those with chronic GVHD tend to have a higher prevalence of multiple health conditions than those without chronic GVHD.[84,85] Physical recovery tends to occur earlier than psychological or work recovery. Full recovery usually takes several years, and about two-thirds of patients are without major limitations by 5 years. Both allogeneic and autologous HCT are associated with a several-fold increase in the risk of premature death; relative mortality decreased with time but remained significantly elevated even 10 years after transplant. The leading cause of death is relapse of primary disease in both allogeneic and autologous HCT patients. Allogeneic HCT patients also continue to die from complications of chronic GVHD while autologous HCT patients more frequently developed secondary malignancies.[84,85] Long-term monitoring of HCT patients is required, both by transplant clinicians and primary care providers who are knowledgeable in the care of these patients, to screen for, prevent and treat late complications when such interventions are available. To assist healthcare professionals providing care to HCT survivors, the CIBMTR (in partnership with leading transplant organizations) published posttransplant care recommendations for adult and pediatric autologous and allogeneic HCT recipients on their website (www.cibmtr.org/posttransplant).

CONCLUSION

HCT offers prolonged disease-free survival, and cure in some cases, for patients with a variety of malignant and non-malignant diseases. These positive results are related to advances in preparative regimens, mobilization strategies, and posttransplant maintenance therapies. With allogeneic HCT, we have learned how to select the best donor and hematopoietic cell source given the recipient's HLA typing, diagnosis and disease status and risk for graft failure and GVHD. Ongoing research will determine best practices in the prevention and treatment of posttransplant complications such as GVHD. With increasing success of HCT, additional research should focus late complications seen in long-term HCT survivors.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is *false* concerning the rationale for hematopoietic cell transplantation?

   A. In some cases, the administration of high doses of chemotherapy can overcome resistance mechanisms that have developed in tumor cells, thereby increasing the likelihood of cure.

   B. Many chemotherapy agents demonstrate a steep dose-response curve with increased anticancer activity at higher doses.

   C. Infusion of hematopoietic stem cells acts as a “rescue” from severe hematopoietic toxicity caused by high-dose chemotherapy.

   D. Immune-mediated effects play a significant role in the anticancer activity of autologous hematopoietic stem cell transplants.

2. Which of the following mobilization regimens would be most appropriate for a 67-year-old man with non-Hodgkin lymphoma in complete remission who has an extensive chemotherapy history?

   A. G-CSF 10 μg/kg twice daily for 5 days followed by GM-CSF 250 μg/m^2/day for 5 days

   B. Cyclophosphamide plus etoposide followed by G-CSF 5 μg/kg/day

   C. No mobilization is necessary because of the high concentration of CD34$^+$ cells in the peripheral blood

   D. G-CSF 10 μg/kg daily with plerixafor 24 mg daily starting on the evening of the fourth day of G-CSF

3. All of the following are advantages of peripheral blood over bone marrow as a source of allogeneic hematopoietic stem cells *except*

   A. More rapid engraftment

   B. Fewer transfusions

   C. Reduced incidence of chronic graft-versus-host disease

   D. Higher numbers of CD34$^+$ cells infused

4. LT is a 19-year-old woman with acute lymphocytic leukemia in second complete remission. Her 25-year-old brother is an 8/8 HLA antigen match, and the patient is scheduled to receive a myeloablative allogeneic hematopoietic cell transplant. Which of the following conditioning regimens would be an appropriate choice?

   A. Cyclophosphamide (120 mg/kg) and total-body irradiation (12 Gy [1200 rad])

   B. Cyclophosphamide (120 mg/kg) and fludarabine (125 mg/m^2)

   C. Fludarabine (125 mg/m^2) and TBI (2 Gy [200 rad])

   D. Cyclophosphamide (120 mg/kg) and busulfan (8 mg/kg)

5. All of the following are advantages of reduced-intensity regimens compared to myeloablative regimens *except*

   A. Improved overall survival

   B. Lower transplant-related mortality

   C. Broader inclusion criteria

   D. Can be used in second transplants

6. JH is a 35-year-old woman with acute myelogenous leukemia (AML) who is day +24 post BuCy and 8/8 HLA-matched unrelated donor transplant with increasing bilirubin, maculopapular skin rash over the trunk and back, and intractable nausea and vomiting. She has no hepatomegaly, and her weight has remained stable over her transplant course. Her current medications include tacrolimus, voriconazole, acyclovir, trimethoprim/sulfamethoxazole, ursodiol, magnesium supplements, and as-needed lorazepam. Her medication regimen has been stable and no new agents have been introduced. She is afebrile and is engrafting with a white blood count of 2,100/mm^3 (2.1 × 10^9/L) and a platelet count of 54,000/mm^3 (54 × 10^9/L). What is the most likely diagnosis?

   A. Sinusoidal obstructive syndrome

   B. Acute graft-versus-host disease

   C. Drug hypersensitivity reaction

   D. Acute infectious cholecystitis

7. For the case in question #7, what is the most appropriate therapeutic management?

   A. Discontinue the trimethoprim/sulfamethoxazole to see if rash resolves and recommend a topical steroid cream

B. Begin broad-spectrum antibiotics

C. Biopsy the liver and consider defibrotide therapy

D. Start prednisone 1 mg/kg/day

8. Which agent is FDA approved for treatment of steroid-refractory acute graft-versus-host disease?

A. Ruxolitinib

B. Etanercept

C. Infliximab

D. Ibrutinib

9. Which of the following statements about stem cell sources is true?

A. UCB has a higher risk of GVHD but a low risk of graft failure

B. Bone marrow as a stem cell source has been correlated with an increase in risk of acute GVHD with an associated decrease in overall survival

C. PBSC used as a stem cell source is associated with more rapid platelet engraftment

D. All stem cell sources are considered equal; there is no benefit to using one stem cell source over another

10. Which of the following posttransplant prophylaxis therapies would be the most appropriate for a 42-year-old patient with BCR-ABL–positive ALL who is at high risk of relapse after myeloablative allogeneic transplant?

A. Donor lymphocyte infusion

B. Dasatinib

C. Rituximab

D. 5-Azacitidine

11. TB is a 57-year-old man with AML who is 19 days post-myeloablative matched related donor peripheral blood stem cell transplant. On examination, it is noted that TB complains of right upper quadrant pain and his abdomen is tight and distended. His laboratory values indicate that he is neutropenic and thrombocytopenic. His complete metabolic panel is normal except for elevated bilirubin and liver enzymes. His nurse also reports that TB has gained 7 kg since his admission. What is the most likely diagnosis for TB?

A. Graft-versus-host disease

B. Pancreatitis

C. Sinusoidal obstructive syndrome

D. Infection

12. Which of the following statements about *acute* GVHD is considered true?

A. The number of T-cells within the stem cell source correlates with the risk for GVHD.

B. The mortality rate directly attributable to GVHD exceeds 80%.

C. The age of the donor and recipient does not impact the risk of GVHD.

   D. Biomarkers are commonly used to predict who will develop GVHD.

13. Which of the following drug regimens would be the most appropriate for GVHD prophylaxis?

   A. Methylprednisolone 2 mg/kg/day

   B. Cyclosporine, methotrexate, and methylprednisolone

   C. Tacrolimus and methotrexate

   D. Posttransplant cyclosporine

14. Which of the following statements about chronic GVHD is true?

   A. It primarily affects the skin, liver, and GI tract.

   B. The incidence of chronic GVHD is decreasing because of alternative donors.

   C. The initial treatment of chronic GVHD is mycophenolate mofetil.

   D. A previous history of acute GVHD increases the risk for chronic GVHD.

15. HS is a 48-year-old man who was just diagnosed with severe chronic GVHD of the skin. His physician would like to initiate therapy immediately. Which of the following choices would be the most appropriate for initial therapy for chronic GVHD?

   A. Prednisone 1 mg/kg/day

   B. Clobetasol cream

   C. Prednisone 0.5 mg/kg/day with mycophenolate

   D. Mycophenolate mofetil.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** D is false because there are no "immune-mediated effects" in autologous HCT. Anti-cancer effects in this setting is based only on the effects of the conditioning regimen. In addition, because the stem cells being used are from the recipient, there is no HLA disparity to cause stimulation of the immune system. All of the other distractors are true. This is discussed in the "Introduction" and "Conditioning Regimens" sections.

2. **D.** D is the correct answer based on patient-specific characteristics (older age, non-Hodgkin lymphoma diagnosis, extensive chemotherapy history), he is at risk for not collecting the minimum number of CD34$^+$ cells. For initial mobilization regimens, plerixafor with G-CSF was associated with higher CD34$^+$ cell yields, fewer apheresis sessions, increased likelihood of achieving CD34$^+$ target yields. Use of combination colony stimulating factors (G-CSF with GM-CSF) or G-CSF combined with chemotherapy are commonly used if a patient has already failed a previous mobilization attempt.

3. **C.** Peripheral blood stem cells are associated with an increased incidence of chronic GVHD when compared to bone marrow. Peripheral blood stems cells are associated with rapid engraftment, fewer platelet transfusions and a higher number of CD34$^+$ cells as discussed in the "Hematopoietic Stem Cells" section.

4. **A.** A is correct because this is the only myeloablative regimen listed (per the question) based on the doses given. The other answers are either reduced intensity or nonmyeloablative. This is discussed in the "Conditioning Regimen" section.

5. **A.** A is correct because studies to date have not consistently demonstrated an increase in overall survival. Although lower nonrelapse mortality has been reported, this is offset in many studies by an increase in relapse rates with reduced-intensity conditioning (compared to myeloablative). Because of the lower incidence of nonrelapse mortality, older patients and those with comorbidities can be transplanted with RIC regimens,

thereby broadening inclusion criteria for transplant. In select patients who have relapsed post-HCT, RIC regimens can also be used in second transplants. This is discussed in the "Conditioning Regimen" section

6. **B.** The patient has symptoms associated with acute GVHD. Maculopapular rash over the trunk and back as well as nausea and vomiting are commonly associated with acute GVHD. Hepatic SOS is not correct because the patient does not have hepatomegaly and her weight has remained stable indicating she does not have significant abdominal ascites. This is not likely infectious as her WBC is within a normal range and the patient is afebrile. Drug-induced hypersensitivity can be ruled out because the rash is contained to the trunk and the back, as well as no new drugs have been introduced into JH's regimen.

7. **D** Since this is likely acute GVHD with organ involvement, the patient should be started in systemic steroids as described in the "Graft-Versus-Host Disease" section.

8. **A.** Of all of the agents listed, only ruxolitinib has received approval for steroid-refractory acute GVHD as described in the "Graft-Versus-Host Disease" section.

9. **B.** B is correct because GVHD is more frequent in patients who are not HLA matched and as the degree of mismatching increases, so does the risk for GVHD. Graft rejection is also correlated with HLA mismatching. Only class I and II HLA antigens are important for allogeneic transplant donors. The most important antigens include those that are listed in D) but also include HLA-C. This is discussed in the "Histocompatibility Testing and Donor Selection" section.

10. **B.** Dasatinib, a tyrosine kinase inhibitor, would be the most appropriate therapy after a transplant in a patient with BCR-ABL positive ALL who is at high risk of relapse. A is not correct because DLI's have not shown to be effective in patients with ALL. Rituximab and 5-azacitidine are used in patients with NHL and AML, respectively.

11. **C.** C is correct as the patients have all of the classic symptoms of SOS as described in the "Sinusoidal Obstruction Syndrome" section.

12. **A.** Increased numbers of T-cells within the graft can increase the risk of GVHD. B is not correct because 20% of deaths after transplant are attributable to GVHD. C is not correct because the older the age of the donor and recipient so does increase the risk of GVHD. Finally, D is not correct because the use of biomarkers to predict GVHD is an area of ongoing investigation and should only be used within the setting of a clinical trial.

13. **C.** Tacrolimus and methotrexate are still commonly used agents in the prevention of GVHD. A is not correct, methylprednisolone at 2 mg/kg/day is a common agent used to treat, not prevent, GVHD. B is not correct because the three drug combination of cyclosporine, methotrexate and steroids has not shown to be more effective than tacrolimus and methotrexate. Finally, single agent cyclosporine was shown to be not as effective as the combination of methotrexate and cyclosporine.

14. **D.** As described in the GVHD section, the risk of chronic GVHD increases if the patient has a history of acute GVHD. Unlike acute GVHD which primarily affects the skin, liver and GI tract, chronic GVHD may affect any organ system. Finally, initial therapy for moderate or severe GVHD is systemic steroids.

15. **A.** A is correct as prednisone 1 mg/kg/day is the treatment of choice for severe chronic GVHD. Topical therapies are not sufficient for this severity of disease and additional medications added to prednisone have not been shown to provide benefit. ECP can be effective in the treatment of skin chronic GVHD but only used in steroid-refractory disease. This is discussed in the "Chronic Graft-Versus-Host Disease" section.
